Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products' liability, negligence, or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Video Contents

Volume One:

Chapter 15: Skin graft

15.1: Harvesting a split-thickness skin graft

Dennis P. Orgill

Chapter 34: Robotics in plastic surgery

34.1: Robotic microsurgery

34.2: Robotic rectus abdominis muscle flap harvest

34.3: Trans-oral robotic surgery

34.4: Robotic latissimus dorsi muscle harvest

34.5: Robotic lymphovenous bypass

Jesse C. Selber

Volume Two:

Chapter 6.2: Facelift: Principles of and surgical approaches to facelift

6.2.1: Parotid masseteric fascia

6.2.2: Anterior incision

6.2.3: Posterior incision

6.2.4: Facelift skin flap

6.2.5: Facial fat injection

Richard J. Warren

6.2.6: Anthropometry, cephalometry, and orthognathic surgery

Jonathon S. Jacobs, Jordan M. S. Jacobs, and Daniel I. Taub

Chapter 6.3: Facelift: Platysma-SMAS plication

6.3.1: Platysma-SMAS plication

Dai M. Davies and Miles G. Berry

Chapter 6.4: Facelift: Facial rejuvenation with loop sutures – the MACS lift and its derivatives

6.4.1: Loop sutures MACS facelift

Patrick L. Tonnard

From Aston SJ, Steinbrech DS, Walden JL, eds. Aesthetic Plastic Surgery, Saunders Elsevier; 2009; with permission from Elsevier

Chapter 6.7: Facelift: SMAS with skin attached – the “high SMAS” technique

6.7.1: The high SMAS technique with septal reset

Fritz E. Barton Jr.

© Fritz E. Barton Jr.

Chapter 6.8: Facelift: Subperiosteal midface lift

6.8.1: Subperiosteal midface lift: Endoscopic temporo-midface

Oscar M. Ramirez

Chapter 9: Blepharoplasty

9.1: Periorbital rejuvenation

Julius Few Jr. and Marco Ellis

© Julius Few Jr.

Chapter 11: Asian facial cosmetic surgery

11.1: Medial epicanthoplasty

11.2: Eyelidplasty: Non-incisional method

11.3: Rhinoplasty

11.4: Subclinical ptosis correction (total)

11.5: Secondary rhinoplasty: Septal extension graft and costal cartilage strut fixed with K-wire

Kyung S. Koh, Jong Woo Choi, and Clyde H. Ishii

Chapter 12: Neck rejuvenation

12.1: Anterior lipectomy

James E. Zins, Colin M. Morrison, and C. J. Langevin

Chapter 13: Structural fat grafting

13.1: Structural fat grafting of the face

Sydney R. Coleman and Alesia P. Saboeiro

Chapter 14: Skeletal augmentation

14.1: Chin implant

Michael J. Yarumchuk

© Mesa J, Havlik R, Mackay D, Buchman S, Losee J, eds. *Atlas of Operative Craniofacial Surgery*, CRC Press, 2019.

14.2: Mandibular angle implant

14.3: Midface skeletal augmentation and rejuvenation

Michael J. Yarumchuk

© Michael J. Yaremchuk

Chapter 16: Open technique rhinoplasty

16.1: Open technique rhinoplasty

Allen L. Van Beek

Chapter 20: Otoplasty and ear reduction

20.1: Setback otoplasty

Leila Kasrai

Chapter 23: Abdominoplasty procedures

23.1: Abdominoplasty

Dirk F. Richter and Alexander Stoff

Chapter 24: Lipoabdominoplasty

24.1: Lipoabdominoplasty (including secondary lipo)

Oswaldo Saldanha, Sérgio Fernando Dantas de Azevedo, Oswaldo Ribeiro Saldanha Filho, Cristianna Bonnetto Saldanha, and Luis Humberto Uribe Morelli

Chapter 26.2: Buttock augmentation: Buttock augmentation with implants

26.2.1: Buttock augmentation

Terrence W. Bruner, Jose Abel De la Peña Salcedo, Constantino G. Mendieta, and Thomas L. Roberts III

Chapter 27: Upper limb contouring

27.1: Brachioplasty

27.2: Upper limb contouring

Joseph F. Capella, Matthew J. Trovato, and Scott Woehrl

Chapter 28: Post-bariatric reconstruction

28.1: Post-bariatric reconstruction – bodylift procedure

J. Peter Rubin and Jonathan W. Toy

© J. Peter Rubin

Volume Three:

Chapter 6: Aesthetic nasal reconstruction

6.1: The three-stage folded forehead flap for cover and lining

6.2: First-stage transfer and intermediate operation

Frederick J. Menick

Chapter 7: Auricular construction

7.1: Total auricular construction

Akira Yamada

Chapter 8: Acquired cranial and facial bone deformities

8.1: Removal of venous malformation enveloping intraconal optic nerve

Renee M. Burke, Robert J. Morin, and S. Anthony Wolfe

Chapter 13: Facial paralysis

13.1: Facial paralysis

Eyal Gur

13.2: Facial paralysis

13.3: Cross facial nerve graft

13.4: Gracilis harvest

Peter C. Neligan

Chapter 14: Pharyngeal and esophageal reconstruction

14.1: Reconstruction of pharyngoesophageal defects with the anterolateral thigh flap

Peirong Yu

Chapter 15: Tumors of the facial skeleton: Fibrous dysplasia

15.1: Surgical approaches to the facial skeleton

Yu-Ray Chen, You-Wei Cheong, and Alberto Córdova-Aguilar

Chapter 17: Local flaps for facial coverage

17.1: Facial artery perforator flap

17.2: Local flaps for facial coverage

Peter C. Neligan

Chapter 21.2: Rotation advancement cheiloplasty

21.2.1: Repair of unilateral cleft lip

Philip Kuo-Ting Chen, M. Samuel Noordhoff, Frank Chun-Shin, Chang, and Fuan Chiang Chan

21.2.2: Unilateral cleft lip repair – anatomic subunit approximation technique

David M. Fisher

Chapter 24: Alveolar clefts

24.1: Unilateral cleft alveolar bone graft

24.2: Mobilized premaxilla after vomer osteotomy prior to setback and splint application

Richard A. Hopper and Gerhard S. Munding

Chapter 26: Velopharyngeal dysfunction

26.1: Velopharyngeal incompetence – 1

26.2: Velopharyngeal incompetence – 2

26.3: Velopharyngeal incompetence – 3

Richard E. Kirschner and Adriane L. Baylis

Chapter 27: Secondary deformities of the cleft lip, nose, and palate

27.1: Abbé flap

27.2: Alveolar bone grafting

27.3: Complete takedown

27.4: Definitive rhinoplasty

Evan M. Feldman, John C. Koshy, Larry H. Hollier Jr., and Samuel Stal

27.5: Thick lip and buccal sulcus deformities

Evan M. Feldman and John C. Koshy

Chapter 36: Pierre Robin Sequence

36.1: Mandibular distraction

Arun K. Gosain and Chad A. Purnell

Chapter 39: Vascular anomalies

39.1: Lip hemangioma

Arin K. Greene

Chapter 43: Reconstruction of urogenital defects: Congenital

43.1: First-stage hypospadias repair with free inner preputial graft

43.2: Second-stage hypospadias repair with tunica vaginalis flap

Mohan S. Gundeti and Michael C. Large

Volume Four:

Chapter 2: Management of lower extremity trauma

2.1: Anterolateral thigh flap harvest

Michel Saint-Cyr

Chapter 3: Lymphatic reconstruction of the extremities

3.1: End-to-side lymphovenous bypass technique

© Cheng M-H, Chang D, Patel K. *Principles and Practice of Lymphedema Surgery*, Elsevier; 2015.

3.2: Recipient site preparation for vascularized lymph node transfer – axilla

© Cheng M-H, Chang D, Patel K. *Principles and Practice of Lymphedema Surgery*, Elsevier; 2015.

3.3: Indocyanine green lymphography

David W. Chang

3.4: Charles procedure

Peter C. Neligan

Chapter 6: Diagnosis and treatment of painful neuroma and nerve compression in the lower extremity

6.1: Diagnosis and treatment of painful neuroma and of nerve compression in the lower extremity 1

6.2: Diagnosis and treatment of painful neuroma and of nerve compression in the lower extremity 2

6.3: Diagnosis and treatment of painful neuroma and of nerve compression in the lower extremity 3

A. Lee Dellon

Chapter 7: Skeletal reconstruction

7.1: Medial femoral condyle/medial geniculate artery osteocutaneous free flap dissection for scaphoid nonunion

Stephen J. Kovach III and L. Scott Levin

Chapter 10: Reconstruction of the chest

10.1: Sternal rigid fixation

David H. Song and Michelle C. Roughton

Chapter 12: Abdominal wall reconstruction

12.1: Component separation innovation

Peter C. Neligan

Chapter 13: Reconstruction of male genital defects

13.1: Complete and partial penile reconstruction

Stan Monstrey, Peter Ceulemans, Nathalie Roche, Philippe Houtmeyers, Nicolas Lumen, and Piet Hoebeke

Volume Five:

Chapter 6: Mastopexy options and techniques

6.1: Circumareolar mastopexy

Kenneth C. Shestak

Chapter 7: One- and two-stage considerations for augmentation mastopexy

7.1: Preoperative markings for a single-stage augmentation mastopexy

W. Grant Stevens

Chapter 10: Reduction mammoplasty with short scar techniques

10.1: SPAIR technique

Dennis C. Hammond

Chapter 11: Gynecomastia surgery

11.1: Ultrasound-assisted liposuction

Charles M. Malata

Chapter 15: One- and two-stage prosthetic reconstruction in nipple-sparing mastectomy

15.1: Pectoralis muscle elevation

15.2: Acellular dermal matrix

15.3: Sizer

Amy S. Colwell

Chapter 16: Skin-sparing mastectomy: Planned two-stage and direct-to-implant breast reconstruction

16.1: Mastectomy and expander insertion: First stage

16.2: Mastectomy and expander insertion: Second stage

Maurizio B. Nava, Giuseppe Catanuto, Angela Pennati, Valentina Visintini Cividin, and Andrea Spano

Chapter 19: Latissimus dorsi flap breast reconstruction

19.1: Latissimus dorsi flap technique

Scott L. Spear[†]

19.2: Markings

19.3: Intraoperative skin paddles

19.4: Tendon division

19.5: Transposition and skin paddles

19.6: Inset and better skin paddle explanation

Neil A. Fine and Michael S. Gart

Chapter 20.2: The deep inferior epigastric artery perforator (DIEAP) flap

20.2.1: The Deep Inferior Epigastric Artery Perforator (DIEAP) flap breast reconstruction

Phillip N. Blondeel and Robert J. Allen, Sr

Chapter 21.2: Gluteal free flaps for breast reconstruction

21.2.1: Superior Gluteal Artery Perforator (SGAP) flap

21.2.2: Inferior Gluteal Artery Perforator (IGAP) flap

Peter C. Neligan

Chapter 21.3: Medial thigh flaps for breast reconstruction

21.3.1: Transverse Upper Gracilis (TUG) flap 1

Peter C. Neligan

21.3.2: Transverse Upper Gracilis (TUG) flap 2

Venkat V. Ramakrishnan

Chapter 23.2: Partial breast reconstruction using reduction and mastopexy techniques

23.2.1: Partial breast reconstruction using reduction mammoplasty

Maurice Y. Nahabedian

23.2.2: Partial breast reconstruction with a latissimus dorsi flap

Neil A. Fine

23.2.3: Partial breast reconstruction with a pedicle TRAM

Maurice Y. Nahabedian

Volume Six:

Chapter 1: Anatomy and biomechanics of the hand

1.1: The extensor tendon compartments

1.2: The contribution of the interosseous and lumbrical muscles to the lateral bands

1.3: Extrinsic flexors and surrounding vasculonervous elements, from superficial to deep

1.4: The lumbrical plus deformity

1.5: The sensory and motor branches of the median nerve in the hand

James Chang, Vincent R. Hentz, Robert A. Chase, and Anaïs Legrand

Chapter 2: Examination of the upper extremity

2.1: Flexor profundus test in a normal long finger

2.2: Flexor sublimis test in a normal long finger

2.3: Extensor pollicis longus test in a normal person

2.4: Test for the Extensor Digitorum Communis (EDC) muscle in a normal hand

2.5: Test for assessing thenar muscle function

2.6: The “cross fingers” sign

2.7: Static Two-Point Discrimination Test (s-2PD Test)

2.8: Moving 2PD Test (m-2PD Test) performed on the radial or ulnar aspect of the finger

2.9: Semmes–Weinstein monofilament test: The patient should sense the pressure produced by bending the filament

2.10: Allen's test in a normal person

2.11: Digital Allen's test

2.12: Scaphoid shift test

2.13: Dynamic tenodesis effect in a normal hand

2.14: The milking test of the fingers and thumb in a normal hand

2.15: Eichhoff test

2.16: Adson test

2.17: Roos test

Ryosuke Kakinoki

Chapter 3: Diagnostic imaging of the hand and wrist

3.1: Scaphoid lunate dislocation

Alphonsus K. Chong and David M. K. Tan

3.2: Right wrist positive midcarpal catch up clunk

Alphonsus K. Chong

Chapter 4: Anesthesia for upper extremity surgery

4.1: Supraclavicular block

Subhro K. Sen

Chapter 5: Principles of internal fixation as applied to the hand and wrist

5.1: Dynamic compression plating and lag screw technique

Christopher Cox

5.2: Headless compression screw

5.3: Locking vs. non-locking plates

Jeffrey Yao and Jason R. Kang

Chapter 7: Hand fractures and joint injuries

7.1: Bennett reduction

7.2: Hemi-Hamate arthroplasty

Warren C. Hammert

Chapter 9: Flexor tendon injury and reconstruction

9.1: Zone II flexor tendon repair

9.2: Incision and feed tendon forward

9.3: Distal tendon exposure

9.4: Six-strand M-tang repair

9.5: Extension–flexion test – wide awake

Jin Bo Tang

Chapter 10: Extensor tendon injuries

10.1: Sagittal band reconstruction

10.2: Setting the tension in extensor indicis transfer

Kai Megerle

Chapter 11: Replantation and revascularization

11.1: Hand replantation

James Chang

Chapter 12: Reconstructive surgery of the mutilated hand

12.1: Debridement technique

James Chang

Chapter 13: Thumb reconstruction: Non-microsurgical techniques

13.1: Osteoplastic thumb reconstruction

13.2: First Dorsal Metacarpal Artery (FDMA) flap

Jeffrey B. Friedrich

Chapter 14: Thumb reconstruction: Microsurgical techniques

14.1: Trimmed great toe

14.2: Second toe for index finger

14.3: Combined second and third toe for metacarpal hand

Nidal F. Al Deek

Chapter 19: Rheumatologic conditions of the hand and wrist

19.1: Extensor tendon rupture and end–side tendon transfer

James Chang

19.2: Silicone metacarpophalangeal arthroplasty

Kevin C. Chung and Evan Kowalski

Chapter 20: Osteoarthritis in the hand and wrist

20.1: Ligament reconstruction tendon interposition arthroplasty of the thumb carpometacarpal joint

James W. Fletcher

Chapter 21: The stiff hand and the spastic hand

21.1: Flexor pronator slide

David T. Netscher

Chapter 22: Ischemia of the hand

22.1: Radial artery sympathectomy

Hee Chang Ahn and Neil F. Jones

22.2: Interposition arterial graft and sympathectomy

Hee Chang Ahn

Chapter 24: Nerve entrapment syndromes

24.1: The manual muscle testing algorithm

24.2: Scratch collapse test – carpal tunnel

Elisabet Hagert

24.3: Injection technique for carpal tunnel surgery

24.4: Wide awake carpal tunnel surgery

Donald Lalonde

24.5: Clinical exam and surgical technique – lacertus syndrome

Elisabet Hagert

24.6: Injection technique for cubital tunnel surgery

24.7: Wide awake cubital tunnel surgery

Donald Lalonde

24.8: Clinical exam and surgical technique – radial tunnel syndrome

24.9: Clinical exam and surgical technique – lateral intermuscular syndrome

24.10: Clinical exam and surgical technique – axillary nerve entrapment

Elisabet Hagert

24.11: Carpal tunnel and cubital tunnel releases in the same patient in one procedure with field sterility: Part 1 – local anesthetic injection for carpal tunnel

24.12: Carpal tunnel and cubital tunnel releases in the same patient in one procedure with field sterility: Part 2 – local anesthetic injection for cubital tunnel

Donald Lalonde and Michael Bezuhyly

Chapter 25: Congenital hand I: Embryology, classification, and principles

25.1: Pediatric trigger thumb release

James Chang

Chapter 27: Congenital hand III: Thumb hypoplasia

27.1: Thumb hypoplasia

Joseph Upton III and Amir Taghinia

Chapter 30: Growth considerations in pediatric upper extremity trauma and reconstruction

30.1: Epiphyseal transplant harvesting technique

Marco Innocenti and Carla Baldrighi

Chapter 31: Vascular anomalies of the upper extremity

31.1: Excision of venous malformation

Joseph Upton III and Amir Taghinia

Chapter 32: Peripheral nerve injuries of the upper extremity

32.1: Suture repair of the cut digital nerve

32.2: Suture repair of the median nerve

Simon Farnebo and Johan Thorfinn

Chapter 35: Free-functioning muscle transfer in the upper extremity

35.1: Gracilis functional muscle harvest

Gregory H. Borschel

Chapter 36: Brachial plexus injuries: Adult and pediatric

36.1: Pediatric: shoulder correct and biceps-to-triceps transfer with preserving intact brachialis

36.2: Adult: results of one-stage surgery for C5 rupture, C6–T1 root avulsion 10 years after

36.3: Nerve transfer results 1

36.4: Nerve transfer results 2

36.5: Nerve transfer results 3

36.6: Nerve transfer results 4

36.7: Nerve transfer results 5

David Chwei-Chin Chuang

Chapter 37: Restoration of upper extremity function in tetraplegia

37.1: The single-stage grip and release procedure

37.2: Postoperative results after single-stage grip release procedure in OCu3–5 patients

Carina Reinholdt and Catherine Curtin

Chapter 38: Upper extremity vascularized composite allotransplantation

38.1: Upper extremity composite tissue allotransplantation

W. P. Andrew Lee and Vijay S. Gorantla

Chapter 39: Hand therapy

39.1: Goniometric measurement

39.2: Threshold testing

Christine B. Novak and Rebecca L. Neiduski

Lecture Video Contents

Volume One:

Chapter 1: Plastic surgery and innovation in medicine

Plastic surgery and innovation in medicine

Peter C. Neligan

Chapter 7: Digital imaging in plastic surgery

Digital imaging in plastic surgery

Daniel Z. Liu

Chapter 15: Skin graft

Skin graft

Peter C. Neligan

Chapter 19: Repair and grafting of peripheral nerve

Nerve injury and repair

Kirsty Usher Boyd, Andrew Yee, and Susan E. Mackinnon

Chapter 20: Reconstructive fat grafting

Reconstructive fat grafting

J. Peter Rubin

Chapter 21: Vascular territories

Vascular territories

Steven F. Morris

Chapter 22: Flap classification and applications

Flap classification and applications

Joon Pio Hong

Chapter 23: Flap pathophysiology and pharmacology

Flap pathophysiology and pharmacology

Cho Y. Pang and Peter C. Neligan

Chapter 24: Principles and techniques of microvascular surgery

Principles and techniques of microvascular surgery

Fu-Chan Wei, Nidal F. Al Deek, and Sherilyn Keng Lin Tay

Chapter 25: Principles and applications of tissue expansion

Principles and applications of tissue expansion

Ivo Alexander Pestana, Louis C. Argenta, and Malcolm W. Marks

Chapter 26: Principles of radiation

Therapeutic radiation: principles, effects, and complications

Gabrielle M. Kane

Chapter 28: Benign and malignant nonmelanocytic tumors of the skin and soft tissue

Benign and malignant nonmelanocytic tumors of the skin and soft tissue

Rei Ogawa

Chapter 31: Facial prosthetics in plastic surgery

Facial prosthetics in plastic surgery

Gordon H. Wilkes

Volume Two:

Chapter 4: Skincare and nonsurgical skin rejuvenation

Skincare and nonsurgical skin rejuvenation

Leslie Baumann and Edmund Weisberg

Chapter 5.2: Injectables and resurfacing techniques: Soft-tissue fillers

Soft-tissue fillers

Trevor M. Born, Lisa E. Airan, and Daniel Suissa

Chapter 5.3: Injectables and resurfacing techniques: Botulinum toxin (BoNT-A)

Botulinum toxin

Michael A. C. Kane

Chapter 5.4: Injectables and resurfacing techniques: Laser resurfacing

Laser resurfacing

Steven R. Cohen, Ahmad N. Saad, Tracy Leong, and E. Victor Ross

Chapter 5.5: Injectables and resurfacing techniques: Chemical peels

Chemical peels

Suzan Obagi

Chapter 6.1: Facelift: Facial anatomy and aging

Anatomy of the aging face

Bryan Mendelson and Chin-Ho Wong

Chapter 6.2: Facelift: Principles of and surgical approaches to facelift

Principles of and surgical approaches to facelift

Richard J. Warren

Chapter 6.3: Facelift: Platysma-SMAS plication

Platysma-SMAS plication

Miles G. Berry

Chapter 6.4: Facelift: Facial rejuvenation with loop sutures – the MACS lift and its derivatives

Facial rejuvenation with loop sutures – the MACS lift and its derivatives

Mark Laurence Jewell

Chapter 6.5: Facelift: Lateral SMASectomy facelift

Lateral SMASectomy facelift

Daniel C. Baker and Steven M. Levine

Chapter 6.6: Facelift: The extended SMAS technique in facial rejuvenation

The extended SMAS technique in facelift

James M. Stuzin

Chapter 6.7: Facelift: SMAS with skin attached – the “high SMAS” technique

SMAS with skin attached – the high SMAS technique

Fritz E. Barton Jr.

Chapter 6.8: Facelift: Subperiosteal midface lift

Subperiosteal midface lift

Alan Yan and Michael J. Yaremchuk

Chapter 6.9: Facelift: Male facelift

Male facelift

Timothy J. Marten and Dino Elyassnia

Chapter 6.10: Facelift: Secondary deformities and the secondary facelift

Secondary deformities and the secondary facelift

Timothy J. Marten and Dino Elyassnia

Chapter 7: Forehead rejuvenation

Forehead rejuvenation

Richard J. Warren

Chapter 8: Endoscopic brow lifting

Endoscopic brow lift

Renato Saltz and Alyssa Lolofie

Chapter 9: Blepharoplasty

Blepharoplasty

Julius Few Jr. and Marco Ellis

Chapter 11: Asian facial cosmetic surgery

Asian facial cosmetic surgery

Clyde H. Ishii

Chapter 12: Neck rejuvenation

Neck rejuvenation

James E. Zins, Joshua T. Waltzman, and Rafael A. Couto

Chapter 13: Structural fat grafting

Structural fat grafting

Sydney R. Coleman and Alesia P. Saboeiro

Chapter 15: Nasal analysis and anatomy

Nasal analysis and anatomy

Rod J. Rohrich

Chapter 19: Secondary rhinoplasty

Secondary rhinoplasty

Ronald P. Gruber, Simeon H. Wall Jr., David L. Kaufman, and David M. Kahn

Chapter 21: Hair restoration

Hair restoration

Jack Fisher

Chapter 22.1: Liposuction: A comprehensive review of techniques and safety

Liposuction

Phillip J. Stephan, Phillip Dauwe, and Jeffrey Kenkel

Chapter 22.2: Correction of liposuction deformities with the SAFE liposuction technique

SAFE liposuction technique

Simeon H. Wall Jr. and Paul N. Afroz

Chapter 23: Abdominoplasty procedures

Abdominoplasty

Dirk F. Richter and Nina Schwaiger

Chapter 25.2: Circumferential approaches to truncal contouring: Belt lipectomy

Belt lipectomy

Al S. Aly, Khalid Al-Zahrani, and Albert Cram

Chapter 25.3: Circumferential approaches to truncal contouring: The lower lipo-bodylift

Circumferential lower bodylift

Dirk F. Richter and Nina Schwaiger

Chapter 25.4: Circumferential approaches to truncal contouring: Autologous buttocks augmentation with purse string gluteoplasty

Purse string gluteoplasty

Joseph P. Hunstad and Nicholas A. Flugstad

Chapter 25.5: Circumferential approaches to truncal contouring: Lower bodylift with autologous gluteal flaps for augmentation and preservation of gluteal contour

Lower bodylift with gluteal flaps

Robert F. Centeno and Jazmina M. Gonzalez

Chapter 26.3: Buttock augmentation: Buttock shaping with fat grafting and liposuction

Buttock shaping with fat grafting and liposuction

Constantino G. Mendieta, Thomas L. Roberts III, and Terrence W. Bruner

Chapter 27: Upper limb contouring

Upper limb contouring

Joseph F. Capella, Matthew J. Trovato, and Scott Woehrl

Chapter 30: Aesthetic genital surgery

Aesthetic genital surgery

Gary J. Alter

Volume Three:

Chapter 10.3: Midface reconstruction: The M. D. Anderson approach

Midfacial reconstruction: The M. D. Anderson approach

Matthew M. Hanasono and Roman Skoracki

Chapter 12: Lip reconstruction

Lip reconstruction

Peter C. Neligan and Lawrence J. Gottlieb

Chapter 14: Pharyngeal and esophageal reconstruction

Pharyngoesophageal reconstruction

Peirong Yu

Chapter 15: Tumors of the facial skeleton: Fibrous dysplasia

Fibrous dysplasia

Alberto Córdova-Aguilar and Yu-Ray Chen

Chapter 17: Local flaps for facial coverage

Local flaps for facial coverage

David W. Mathes

Chapter 19: Facial transplant

Facial transplant

Michael Sosin and Eduardo D. Rodriguez

Chapter 32: Nonsyndromic craniosynostosis

Nonsyndromic craniosynostosis

Patrick A. Gerety, Jesse A. Taylor, and Scott P. Bartlett

Chapter 36: Pierre Robin Sequence

Pierre Robin sequence

Chad A. Purnell and Arun K. Gosain

Chapter 39: Vascular anomalies

Vascular anomalies

Arin K. Greene and John B. Mulliken

Volume Four:

Chapter 2: Management of lower extremity trauma

Management of lower extremity trauma

Yoo Joon Sur, Shannon M. Colohan, and Michel Saint-Cyr

Chapter 15: Surgery for gender identity disorder

Surgery for gender identity disorder

Loren S. Schechter

Chapter 16: Pressure sores

Pressure sores

Robert Kwon, Juan L. Rendon, and Jeffrey E. Janis

Chapter 17: Perineal reconstruction

Perineal reconstruction

Hakim K. Said and Otway Louie

Volume Five:

Chapter 5: Breast augmentation with autologous fat grafting

Breast augmentation with autologous fat grafting

E. Delay

Chapter 6: Mastopexy options and techniques

Mastopexy

Robert Cohen

Chapter 9: Reduction mammoplasty with inverted-T techniques

Reduction mammoplasty with inverted-T techniques

Maurice Y. Nahabedian

Chapter 15: One- and two-stage prosthetic reconstruction in nipple-sparing mastectomy

Prosthetic reconstruction in nipple-sparing mastectomy

Amy S. Colwell

Chapter 20.1: Abdominally based free flaps: Introduction

Abdominally-based autologous breast reconstruction

Maurice Y. Nahabedian, Phillip N. Blondeel, and David H. Song

Chapter 20.2: The deep inferior epigastric artery perforator (DIEAP) flap

Abdominally-based autologous breast reconstruction

Maurice Y. Nahabedian, Phillip N. Blondeel, and David H. Song

Chapter 20.3: The superficial inferior epigastric artery (SIEA) flap

Abdominally-based autologous breast reconstruction

Maurice Y. Nahabedian, Phillip N. Blondeel, and David H. Song

Chapter 20.4: The free TRAM flap

Abdominally-based autologous breast reconstruction

Maurice Y. Nahabedian, Phillip N. Blondeel, and David H. Song

Chapter 25: Radiation therapy considerations in the setting of breast reconstruction

Radiation therapy in breast reconstruction

Steven Kronowitz

Volume Six:

Chapter 7: Hand fractures and joint injuries

Hand fractures and joint injuries

Joseph S. Khouri and Warren C. Hammert

Chapter 13: Thumb reconstruction: Non-microsurgical techniques

Thumb reconstruction

Nicholas B. Vedder and Jeffrey B. Friedrich

Chapter 21: The stiff hand and the spastic hand

The stiff hand

David T. Netscher, Kenneth W. Donohue, and Dang T. Pham

Chapter 24: Nerve entrapment syndromes

Tips and pearls on common nerve compressions*Elisabet Hagert and Donald Lalonde*

Chapter 30: Growth considerations in pediatric upper extremity trauma and reconstruction

Growth considerations in pediatric upper extremity trauma and reconstruction*Marco Innocenti and Carla Baldrighi*

Chapter 33: Nerve transfers

Nerve injury and repair*Kirsty Usher Boyd, Andrew Yee, and Susan E. Mackinnon*

Chapter 37: Restoration of upper extremity function in tetraplegia

Restoration of upper extremity function in tetraplegia*Carina Reinholdt and Catherine Curtin*

Preface to the Fourth Edition

When I wrote the preface to the 3rd edition of this book, I remarked how honored and unexpectedly surprised I was to be the Editor of this great series. This time 'round, I'm equally grateful to carry this series forward. When Elsevier called me and suggested it was time to prepare the 4th edition, my initial reaction was that this was way too soon. What could possibly have changed in Plastic Surgery since the 3rd edition was launched in 2012? As it transpires, there have been many developments and I hope we have captured them in this edition.

We have an extraordinary specialty. A recent article by Chadra, Agarwal and Agarwal entitled "Redefining Plastic Surgery" appeared in *Plastic and Reconstructive Surgery—Global Open*. In it they gave the following definition: "Plastic surgery is a specialized branch of surgery, which deals with deformities, defects and abnormalities of the organs of perception, organs of action and the organs guarding the external passages, besides innovation, implantation, replantation and transplantation of tissues, and aims at restoring and improving their form, function and the esthetic appearances." This is an all-encompassing but very apt definition and captures the enormous scope of the specialty.¹

In the 3rd edition, I introduced volume editors for each of the areas of the specialty because the truth is that one person can no longer be an expert in all areas of this diverse specialty, and I'm certainly not. I think this worked well because the volume editors not only had the expertise to present their area of subspecialty in the best light, but they were tuned in to what was new and who was doing it. We have continued this model in this new edition. Four of the seven volume editors from the previous edition have again helped to bring the latest and the best to this edition: Drs Gurtner, Song, Rodriguez, Losee, and Chang have revised and updated their respective volumes with some chapters remaining, some extensively revised, some added, and some deleted. Dr. Peter Rubin has replaced Dr. Rick Warren to compile the Aesthetic volume (Vol. 2). Dr. Warren did a wonderful job in corralling this somewhat disparate, yet vitally important, part of our specialty into the Aesthetic volume in the 3rd edition but felt that the task of doing it again, though a labor of love, was more than he wanted to take on. Similarly, Dr. Jim Grotting who did a masterful job in the last edition on the Breast volume, decided that doing a major revision should be undertaken by someone with a fresh perspective and Dr. Maurice Nahabedian stepped into that breach. I hope you will like the changes you see in both of these volumes.

Dr. Allen Van Beek was the video editor for the last edition and he compiled an impressive array of movies to complement the text. This time around, we wanted to go a step further and though we've considerably expanded the list of

videos accompanying the text (there are over 170), we also added the idea of lectures accompanying selected chapters. What we've done here is to take selected key chapters and include the images from that chapter, photos and artwork, and create a narrated presentation that is available online; there are annotations in the text to alert the reader that this is available. Dr. Daniel Liu, who has taken over from Dr. Van Beek as multimedia editor (rather than video editor) has done an amazing job in making all of this happen. There are over 70 presentations of various key chapters online, making it as easy as possible for you, the reader, to get as much knowledge as you can, in the easiest way possible from this edition. Many of these presentations have been done by the authors of the chapters; the rest have been compiled by Dr. Liu and myself from the content of the individual chapters. I hope you find them useful.

The reader may wonder how this all works. To plan this edition, the Elsevier team, headed by Belinda Kuhn, and I, convened a face-to-face meeting in San Francisco. The volume editors, as well as the London based editorial team, were present. We went through the 3rd edition, volume by volume, chapter by chapter, over an entire weekend. We decided what needed to stay, what needed to be added, what needed to be revised, and what needed to be changed. We also decided who should write the various chapters, keeping many existing authors, replacing others, and adding some new ones; we did this so as to really reflect the changes occurring within the specialty. We also decided on practical changes that needed to be made. As an example, you will notice that we have omitted the complete index for the 6 Volume set from Volumes 2-6 and highlighted only the table of contents for that particular volume. The complete index is of course available in Volume 1 and fully searchable online. This allowed us to save several hundred pages per volume, reducing production costs and diverting those dollars to the production of the enhanced online content.

In my travels around the world since the 3rd edition was published, I've been struck by what an impact this publication has had on the specialty and, more particularly, on training. Everywhere I go, I'm told how the text is an important part of didactic teaching and a font of knowledge. It is gratifying to see that the 3rd edition has been translated into Portuguese, Spanish, and Chinese. This is enormously encouraging. I hope this 4th edition continues to contribute to the specialty, remains a resource for practicing surgeons, and continues to prepare our trainees for their future careers in Plastic Surgery.

List of Editors

Editor-in-Chief

Peter C. Neligan, MB, FRCS(I), FRCSC, FACS

Professor of Surgery
Department of Surgery, Division of Plastic Surgery
University of Washington
Seattle, WA, USA

Volume 4: Lower Extremity, Trunk, and Burns

David H. Song, MD, MBA, FACS

Regional Chief, MedStar Health
Plastic and Reconstructive Surgery
Professor and Chairman
Department of Plastic Surgery
Georgetown University School of Medicine
Washington, DC, USA

Volume 1: Principles

Geoffrey C. Gurtner, MD, FACS

Johnson and Johnson Distinguished Professor of
Surgery and Vice Chairman,
Department of Surgery (Plastic Surgery)
Stanford University
Stanford, CA, USA

Volume 5: Breast

Maurice Y. Nahabedian, MD, FACS

Professor and Chief
Section of Plastic Surgery
MedStar Washington Hospital Center
Washington, DC, USA;
Vice Chairman
Department of Plastic Surgery
MedStar Georgetown University Hospital
Washington, DC, USA

Volume 2: Aesthetic

J. Peter Rubin, MD, FACS

UPMC Professor of Plastic Surgery
Chair, Department of Plastic Surgery
Professor of Bioengineering
University of Pittsburgh
Pittsburgh, PA, USA

Volume 6: Hand and Upper Extremity

James Chang, MD

Johnson & Johnson Distinguished
Professor and Chief
Division of Plastic and Reconstructive Surgery
Stanford University Medical Center
Stanford, CA, USA

Volume 3: Craniofacial, Head and Neck Surgery

Eduardo D. Rodriguez, MD, DDS

Helen L. Kimmel Professor of Reconstructive
Plastic Surgery
Chair, Hansjörg Wyss Department of Plastic
Surgery
NYU School of Medicine
NYU Langone Medical Center
New York, NY, USA

Multimedia editor

Daniel Z. Liu, MD

Plastic and Reconstructive Surgeon
Cancer Treatment Centers of America at Midwest-
ern Regional Medical Center
Zion, IL, USA

Volume 3: Pediatric Plastic Surgery

Joseph E. Losee, MD

Ross H. Musgrave Professor of Pediatric Plastic
Surgery
Department of Plastic Surgery
University of Pittsburgh Medical Center;
Chief Division of Pediatric Plastic Surgery
Children's Hospital of Pittsburgh
Pittsburgh, PA, USA

List of Contributors

The editors would like to acknowledge and offer grateful thanks for the input of all previous editions' contributors, without whom this new edition would not have been possible.

Emory University School of Medicine
Emory Aesthetic Center at Paces
Atlanta, Georgia, USA

Suzan Obagi, MD

Associate Professor of Dermatology
Dermatology
University of Pittsburgh;
Associate Professor of Plastic Surgery
Plastic Surgery
University of Pittsburgh
Pittsburgh, PA, USA

Sabina Aparecida Alvarez de Paiva, MD

Resident of Plastic Surgery
Plastic Surgery Service Dr. Ewaldo Bolivar de
Souza Pinto
São Paulo, Brazil

Galen Perdikis, MD

Assistant Professor of Surgery
Division of Plastic Surgery
Emory University School of Medicine
Atlanta, GA, USA

Jason Posner, MD, FACS

Private Practice
Boca Raton, FL, USA

Dirk F. Richter, MD, PhD

Clinical Professor of Plastic Surgery
University of Bonn
Director and Chief
Dreifaltigkeits-Hospital
Wesseling, Germany

Thomas L. Roberts III, FACS

Plastic Surgery Center of the Carolinas
Spartanburg, SC, USA

Jocelyn Celeste Ledezma Rodriguez, MD

Private Practice
Guadalajara, Jalisco, Mexico

Rod J. Rohrich, MD

Clinical Professor and Founding Chair
Department of Plastic Surgery
Distinguished Teaching Professor
University of Texas Southwestern Medical Center
Founding Partner
Dallas Plastic Surgery Institute
Dallas, TX, USA

E. Victor Ross, MD

Director of Laser and Cosmetic Dermatology
Scripps Clinic
San Diego, CA, USA

J. Peter Rubin, MD, FACS

Chief
Plastic and Reconstructive Surgery
University of Pittsburgh Medical Center;
Associate Professor
Department of Surgery
University of Pittsburgh
Pittsburgh, PA, USA

Ahmad N. Saad, MD

Private Practice
FACES+ Plastic Surgery
Skin and Laser Center
La Jolla, CA, USA

Alesia P. Saboeiro, MD

Attending Physician
Private Practice
New York, NY, USA

Cristianna Bonnetto Saldanha, MD

Plastic Surgery Service Dr. Osvaldo Saldanha
São Paulo, Brazil

Osvaldo Saldanha, MD, PhD

Director of Plastic Surgery Service Dr. Osvaldo
Saldanha;
Professor of Plastic Surgery Department
Universidade Metropolitana de Santos
- UNIMES
São Paulo, Brazil

Renato Saltz, MD, FACS

Saltz Plastic Surgery
President
International Society of Aesthetic Plastic Surgery
Adjunct Professor of Surgery
University of Utah
Past-President, American Society for Aesthetic
Plastic Surgery
Salt Lake City and Park City, UT, USA

Paulo Rodamilans Sanjuan MD

Chief Resident of Plastic Surgery
Plastic Surgery Service Dr. Ewaldo Bolivar de
Souza Pinto
São Paulo, Brazil

Nina Schwaiger, MD

Senior Specialist in Plastic and Aesthetic
Surgery
Department of Plastic Surgery
Dreifaltigkeits-Hospital Wesseling
Wesseling, Germany

Douglas S. Steinbrech, MD, FACS

Gotham Plastic Surgery
New York, NY, USA

Phillip J. Stephan, MD

Clinical Faculty
Plastic Surgery
UT Southwestern Medical School;
Plastic Surgeon
Texoma Plastic Surgery
Wichita Falls, TX, USA

David Gonzalez Sosa, MD

Plastic and Reconstructive Surgery
Hospital Quirónsalud Torrevieja
Alicante, Spain

James M. Stuzin, MD

Associate Professor of Surgery
(Plastic) Voluntary
University of Miami Leonard M. Miller School of
Medicine
Miami, FL, USA

Daniel Suissa, MD, MSc

Clinical Instructor
Section of Plastic and Reconstructive Surgery
Yale University
New Haven, CT, USA

Charles H. Thorne, MD

Associate Professor of Plastic Surgery
Department of Plastic Surgery
NYU School of Medicine
New York, NY, USA

Ali Totonchi, MD

Assistant Professor
Plastic Surgery
Case Western Reserve University;
Medical Director Craniofacial Deformity Clinic
Plastic Surgery
MetroHealth Medical center
Cleveland, OH, USA

Jonathan W. Toy, MD, FRCSC

Program Director, Plastic Surgery Residency
Program Assistant Clinical Professor
University of Alberta
Edmonton, Alberta, Canada

Matthew J. Trovato, MD

Dallas Plastic Surgery Institute
Dallas, TX, USA

Simeon H. Wall Jr., MD, FACS

Director
The Wall Center for Plastic Surgery;
Assistant Clinical Professor
Plastic Surgery
LSU Health Sciences Center at Shreveport
Shreveport, LA, USA

Joshua T. Waltzman, MD, MBA

Private Practice
Waltzman Plastic and Reconstructive Surgery
Long Beach, CA, USA

Richard J. Warren, MD, FRCSC

Clinical Professor
Division of Plastic Surgery
University of British Columbia
Vancouver, British Columbia, Canada

Edmund Weisberg, MS, MBE

University of Pennsylvania
Philadelphia, PA, USA

Scott Woehrle, MS BS

Physician Assistant
Department of Plastic Surgery
Joseph Capella Plastic Surgery
Ramsey, NJ, USA

Chin-Ho Wong, MBBS, MRCS, MMed(Surg), FAMS(Plast Surg)

W Aesthetic Plastic Surgery
Mt Elizabeth Novena Specialist Center
Singapore

Alan Yan, MD

Former Fellow
Adult Reconstructive and Aesthetic
Craniofacial Surgery
Division of Plastic and Reconstructive Surgery
Massachusetts General Hospital
Boston, MA, USA

Michael J. Yaremchuk, MD

Chief of Craniofacial Surgery
Massachusetts General Hospital;
Clinical Professor of Surgery
Harvard Medical School;
Program Director
Harvard Plastic Surgery Residency Program
Boston, MA, USA

James E. Zins, MD

Chairman
Department of Plastic Surgery
Dermatology and Plastic Surgery Institute
Cleveland Clinic
Cleveland, OH, USA

VOLUME THREE**Neta Adler, MD**

Senior Surgeon
Department of Plastic and Reconstructive
Surgery
Hadassah University Hospital
Jerusalem, Israel

Ahmed M. Afifi, MD

Assistant Professor of Plastic Surgery
Department of Surgery
University of Wisconsin
Madison, WI, USA;
Associate Professor
Department of Plastic Surgery
Cairo University
Cairo, Egypt

Marta Alvarado, DDS, MS

Department of Orthodontics
Facultad de Odontología
Universidad de San Carlos de Guatemala
Guatemala

Eric Arnaud, MD

Pediatric Neurosurgeon and Co-Director
Unité de Chirurgie Craniofaciale
Hôpital Necker Enfants Malades
Paris, France

Stephen B. Baker, MD, DDS

Associate Professor and Program Director
Co-Director Inova Hospital for Children
Craniofacial Clinic
Department of Plastic Surgery
Georgetown University Hospital
Georgetown, WA, USA

Scott P. Bartlett, MD

Professor of Surgery
Surgery
University of Pennsylvania;
Chief Division of Plastic Surgery
Surgery
Children's Hospital of Philadelphia
Philadelphia, PA, USA

Bruce S. Bauer, MD

Chief
Division of Plastic Surgery
NorthShore University HealthSystem
Highland Park;
Clinical Professor of Surgery
Department of Surgery
University of Chicago Pritzker School of
Medicine
Chicago, IL, USA

Adriane L. Baylis, PhD

Speech Scientist
Section of Plastic and Reconstructive Surgery
Nationwide Children's Hospital
Columbus, OH, USA

Mike Bentz, MD, FAAP, FACS

Interim Chairman
Department of Surgery
University of Wisconsin;
Chairman Division of Plastic Surgery
Department of Surgery
University of Wisconsin
Madison, WI, USA

Craig Birgfeld, MD, FACS

Associate Professor, Pediatric Plastic and
Craniofacial Surgery
Seattle Children's Hospital
Seattle, WA, USA

William R. Boysen, MD

Resident Physician, Urology
University of Chicago Medicine
Chicago, IL, USA

James P. Bradley, MD

Professor and Chief
Section of Plastic and Reconstructive Surgery
Temple University
Philadelphia, PA, USA

Edward P. Buchanan, MD

Division of Plastic Surgery
Baylor College of Medicine
Houston, TX, USA

Michael R. Bykowski, MD, MS

Plastic Surgery Resident
Plastic Surgery
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

Edward J. Caterson, MD, PhD

Director of Craniofacial Surgery
Division of Plastic Surgery
Brigham and Women's Hospital
Boston, MA, USA

Rodney K. Chan, MD

Chief Plastic and Reconstructive Surgery
Clinical Division and Burn Center
United States Army Institute of Surgical
Research
Joint Base San Antonio, TX, USA

Edward I. Chang, MD

Assistant Professor
Department of Plastic Surgery
The University of Texas M. D. Anderson Cancer
Center
Houston, TX, USA

Constance M. Chen, MD, MPH

Director of Microsurgery
Plastic and Reconstructive Surgery
New York Eye and Ear Infirmary of Mt Sinai;
Clinical Assistant Professor
Plastic and Reconstructive Surgery
Weil Medical College of Cornell University;
Clinical Assistant Professor
Plastic and Reconstructive Surgery
Tulane University School of Medicine
New York, NY, USA

Yu-Ray Chen, MD

Professor of Surgery
Plastic and Reconstructive Surgery
Chang Gung Memorial Hospital
Taoyuan City, Taiwan

Philip Kuo-Ting Chen, MD

Professor
Craniofacial Center
Chang Gung Memorial Hospital
Taoyuan City, Taiwan

Ming-Huei Cheng, MD, MBA

Professor
Division of Reconstructive Microsurgery
Department of Plastic and Reconstructive
Surgery
Chang Gung Memorial Hospital
Taoyuan City, Taiwan

Gerson R. Chinchilla, DDS MS

Director
Department of Orthodontics
Facultad de Odontología
Universidad de San Carlos de Guatemala
Guatemala

Peter G. Cordeiro, MD

Chief
Plastic and Reconstructive Surgery
Memorial Sloan Kettering Cancer Center;
Professor of Surgery
Surgery
Weil Medical College of Cornell University
New York, NY, USA

Alberto Córdova-Aguilar, MD, MPH

Attending Plastic Surgeon
Surgery
Faculty of Medicine Ricardo Palma University
Lima, Peru

Edward H. Davidson, MA(Cantab), MBBS

Resident Plastic Surgeon
Department of Plastic Surgery
University of Pittsburgh
Pittsburgh, PA, USA

Sara R. Dickie, MD

Clinician Educator
Surgery
University of Chicago Hospital Pritzker School of Medicine;
Attending Surgeon
Section of Plastic and Reconstructive Surgery
NorthShore University HealthSystem
Northbrook, IL, USA

Risal S. Djohan, MD

Microsurgery Fellowship Program Director
Plastic Surgery
Cleveland Clinic;
Surgery ASC Quality Improvement Officer
Plastic Surgery
Cleveland Clinic
Cleveland, OH, USA

Amir H. Dorafshar, MBChB, FACS, FAAP

Associate Professor
Plastic and Reconstructive Surgery
Johns Hopkins Medical Institute;
Assistant Professor
Plastic Surgery
R Adams Cowley Shock Trauma Center
Baltimore, MD, USA

Jeffrey A. Fearon, MD

Director
The Craniofacial Center
Dallas, TX, USA

Alexander L. Figueroa, DMD

Craniofacial Orthodontist
Rush Craniofacial Center
Rush University Medical Center
Chicago, IL, USA

Alvaro A. Figueroa, DDS, MS

Co-Director
Rush Craniofacial Center
Rush University Medical Center
Chicago, IL, USA

David M. Fisher, MB, BCh, FRCS, FACS

Medical Director Cleft Lip and Palate Program
Plastic Surgery
Hospital for Sick Children;
Associate Professor
Surgery
University of Toronto
Toronto, Ontario, Canada

Roberto L. Flores, MD

Associate Professor of Plastic Surgery
Director of Cleft Lip and Palate
Hansjörg Wyss Department of Plastic Surgery
NYU Langone Medical Center
New York, NY, USA

Andrew Foreman, B. Physio, BMBS(Hons), PhD, FRACS

Consultant Surgeon, Department of
Otolaryngology - Head and Neck Surgery
University of Adelaide,
Royal Adelaide Hospital,
Adelaide, SA, Australia

Patrick A. Gerety, MD

Assistant Professor of Surgery
Division of Plastic and Reconstructive Surgery
Indiana University and Riley Hospital for Children
Philadelphia, PA, USA

Jesse A. Goldstein, MD

Chief Resident
Department of Plastic Surgery
Georgetown University Hospital
Washington, DC, USA

Arun K. Gosain, MD

Chief
Division of Plastic Surgery
Ann and Robert H. Lurie Children's Hospital of Chicago
Chicago, IL, USA

Lawrence J. Gottlieb, MD

Professor of Surgery
Department of Surgery
Section of Plastic and Reconstructive Surgery
University of Chicago
Chicago, IL, USA

Arin K. Greene, MD, MMSc

Department of Plastic and Oral Surgery
Boston Children's Hospital;
Associate Professor of Surgery
Harvard Medical School
Boston, MA, USA

Patrick J. Gullane, MD, FRCS

Wharton Chair in Head and Neck Surgery
Professor of Surgery, Department of
Otolaryngology - Head and Neck Surgery
University of Toronto
Toronto, Ontario, Canada

Mohan S. Gundeti, MB, MCh, FEBU, FRCS(Urol), FEAPU

Associate Professor
Department of Orthopedic Surgery
Stanford Hospital & Clinics
Redwood City, CA, USA

Acknowledgments

My wife, Gabrielle Kane, has always been my rock. She not only encourages me in my work but gives constructive criticism bolstered by her medical expertise as well as by her knowledge and training in education. I can never repay her. The editorial team at Elsevier have made this series possible. Belinda Kuhn leads the group of Alexandra Mortimer, Louise Cook, and the newest addition to the team, Sam Crowe. The Elsevier production team has also been vital in moving this project along. The volume editors, Geoff Gurtner, Peter Rubin, Ed Rodriguez, Joe Losee, David Song, Mo Nahabedian, Jim Chang, and Dan Liu have shaped and refined this edition, making vital changes to keep the series relevant and up-to-date. My colleagues in the University of Washington, headed by Nick Vedder, have provided continued encouragement and support. Finally, and most importantly, the residents and fellows who pass through our program keep us on our toes and ensure that we give them the best possible solutions to their questions.

Peter C. Neligan, MB, FRCS(I), FRCSC, FACS

I want to thank my wife Kathryn for her unfailing good cheer and support on the nights and weekends I worked on this volume. I would also like to thank my sons, Cole, Pierce and Jack, for their limitless curiosity and energy, which continually challenge my view of the world. I am grateful to my assistant, Theresa Carlomagno, for her skill in helping me juggle too many things. And I need to acknowledge the Elsevier staff, especially Sam Crowe, for his patience in dealing with me.

Geoffrey C. Gurtner, MD, FACS

*Dedicated to future plastic surgeons. Take up the torch
and lead us forward!*

Plastic surgery and innovation in medicine

Peter C. Neligan

Access video lecture content for this chapter online at expertconsult.com

SYNOPSIS

- There is a major difference between research and innovation, though the two are often interrelated.
- Most advances in surgery come from innovation rather than basic research.
- Surgical innovation is one of the defining features of plastic surgery.
- Surgical innovation is made safe by defining principles.
- A detailed knowledge of anatomy is a major factor on which these principles are based.
- A balance between out-of-the-box thinking and conservative deliberation is the perfect milieu to effect change yet keep perspective.

Introduction

There was a time when a general surgeon took care of everything; from fractures to furuncles, skin grafts to sigmoidoscopies, cysts to cancers. Since that time, everything has become specialized. Even in our specialty, the era of subspecialization has already arrived. Despite this, in some ways plastic surgeons are the last general surgeons. We are not confined to an organ or system. Nor are we linked to a disease, and this separates us from almost every other medical specialty. With some exceptions, plastic surgery operations are not always the same. We regularly perform operations that we've never done in precisely the same way before and will likely never do in exactly the same way again. We almost always have completed some elements of the surgery before, or we may add elements from another sphere of surgery to create a new approach to a problem. The adoption of endoscopic techniques is an example of this.

Sometimes this innovation is born of necessity, the challenge of solving a unique problem for which there is no standard or well-accepted solution. Sometimes it is born of the will to do something better, to solve a problem in such a way that is better than what has been done before. The time

of greatest surgical innovation in most specialties is in times of war and natural disaster when we are presented with problems in such overwhelming numbers that we have to come up with some solution that enables us to deal with such large numbers. While this is acceptable in these unique situations, the concept of innovation at other times is sometimes shocking to non-medical people. To the uninitiated it may seem cavalier, even dangerous. However, these innovations are based on principles that we learn in our training and that we apply in our practice. That is the magic of plastic surgery and what many people have called the art of plastic surgery. It is in many ways similar to the musician who tries a new way of interpreting a song or a painter who uses new materials to paint a picture, though my personal view is that plastic surgery is more a craft than an art. Of course this type of surgical innovation raises ethical issues and it is something with which many institutions are struggling, not merely in the domain of plastic surgery but in the field of surgery in general.¹ In 2008, a position statement of the Society of University Surgeons (SUS) recommended the creation of institutional surgical innovation committees (SICs) to ensure appropriate oversight of surgical innovations. It is surprising that several years later, only 23% of surgery departments had SICs in place and many department chairs were unaware of the position statement.² Many institutions already have processes and protocols in place to oversee and regulate innovation.³ When is innovation in surgery ethical and when is it not? This has already been the source of much discussion in the literature.⁴⁻⁶ How far can we safely push the envelope? That particular discussion is beyond the scope of this chapter. In order to push the frontiers of surgery it is important to strike a balance between necessary oversight of research practices and a supportive environment where research can flourish.

Innovation and research

What is the difference between innovation and research? Wikipedia (<http://en.wikipedia.org/wiki/Research>) defines

research as follows: “Research comprises ‘creative work undertaken on a systematic basis in order to increase the stock of knowledge, including knowledge of humans, culture and society, and the use of this stock of knowledge to devise new applications.’” The definition of innovation is much different: (<http://en.wikipedia.org/wiki/Innovation>) “The term ‘innovation’ can be defined as something original and more effective and, as a consequence, new, that ‘breaks into’ the market or society.” It may refer to an incremental emergent change or radical and revolutionary changes in thinking, products, processes, or organizations.” Though we would like to think that innovation comes from research, this is not always the case. It’s not just in medicine that this happens. For example, innovations in the computer industry are often simple changes introduced to facilitate a task, only to sometimes completely change how things are done. For instance, Apple recently redesigned laptop batteries to completely fill the irregular space available and thereby prolong battery life. They have also revolutionized how we listen to music, and how we even purchase it. New changes happen all the time; they are sometimes incremental and sometimes game-changing.

Most of the surgical innovations we see are not the result of research and, historically, most of the major advances in surgery have been the result of innovation rather than basic research. In fact, not infrequently, an innovation, often conceived on the fly, is subsequently subjected to more rigorous study. A surgeon may design a new operation or, for example, a new flap. This may be a variation on an old procedure or sometimes something completely new. As I have already said, it may have been forced on the surgeon because of the circumstances of the case. There may be no other way to solve the problem. When it works, the surgeon decides to design a study to explain why the procedure worked or to describe the blood supply of the flap. Though one could argue that this is not the ideal way to do things, it certainly happens^{7,8} and is merely a reflection of the dynamic nature of surgical innovation. Innovation may be planned or, in the case of this example and as happens probably more frequently, may be made on the fly. Research may be innovative. A researcher may design a novel experiment to probe a theory, an approach to the problem that has not been explored before. This is also innovation and is more commonly how research and innovation are linked. An innovative idea is subjected to the scientific method that research demands. What makes an innovator? It has been said that the characteristics that most major innovators have in common include: 1) the ability to recognize an idea, 2) persistence in developing the strategy and 3) commitment to the project, and final completion of a response to the problem or problems in question.⁹

Innovation and plastic surgery

The history of plastic surgery, at least the history of modern plastic surgery, is one of constant development. We regularly devise new ways of dealing with a particular problem. We develop a technique, perfect it and then either lose it to some other group, or give it away. There are numerous examples of this, from cleft surgery to microsurgery, from hand surgery to craniofacial surgery. While some see this as a major problem, I would argue that it is the lifeblood of plastic surgery. We are constantly developing new solutions to diverse problems.

Some of these problems are generated from within our own practices, some come from our interaction with other specialties. We develop solutions and frequently allow those other specialties to run with the ball while we go on to something else. The facility to adapt is important in all spheres. For example, this ability to adapt, change and incorporate new ideas is what has made English such a dominant language. It is the reason that Apple Inc. has become an industry leader. This is the essence of innovation. There are numerous examples in biology that underline how the power of adaption is the power of survival. For plastic surgery the same holds true and while some fear the demise of the specialty, I would argue that while we continue to adapt and develop, there will always be a place for plastic surgery.

Vascularized composite allotransplantation

In research we work with models; models of disease, models of a procedure. Animal models provide a means by which we can study the process we are interested in addressing in our patients. Occasionally, in order to solve a problem, we move to models that are perhaps less relevant to our everyday clinical practice. For example, most people don’t realize that the first kidney transplant was performed by Dr. Joseph Murray (Fig. 1.1), a plastic surgeon at the Peter Bent Brigham Hospital in Boston,¹⁰ now the Brigham and Women’s Hospital. People are generally intrigued by this snippet of information. What was a plastic surgeon doing transplanting kidneys? How could this be? His practice as a plastic surgeon raised questions in his mind surrounding transplantation. His experience treating burn patients sent back from the war during World War II gave him wide exposure to skin grafting and raised issues of immune rejection that he would later find ways to address. In trying to work out the immunology of skin grafts, he moved to a single organ model, the kidney, in order to answer the question he had originally conceived. This

Fig. 1.1 Dr. Joseph Murray.

culminated in the first successful kidney transplant performed from one twin to another by Dr. Murray at the Peter Bent Brigham Hospital in Boston in 1954. Having helped develop the specialty of transplantation, he went on to perform the world's first successful allograft in 1959 and the world's first cadaveric renal transplant in 1962. Dr. Murray ultimately returned to his roots, the practice of plastic surgery, and was awarded the Nobel Prize in Physiology or Medicine in 1990 for his contribution to the science of transplantation.

Now, that wheel has turned full circle and plastic surgery is, once again, in the mainstream of transplant innovation (see Chapter 32). Hand and face transplants have become a reality. The first hand transplant was performed in 1998¹¹ and the first face transplant in 2005.¹² While these procedures are still not in the mainstream of practice, it is interesting that there are 20 institutions designated as VCA (vascularized composite allograft) transplant centers in the US and three of them have established their programs as standard of care rather than submitting them under an institutional review board (IRB) protocol. This has been accepted by UNOS (United Network for Organ Sharing), the private, non-profit organization that manages the US organ transplant system under contract with the federal government. VCA is designed to address those reconstructions that we cannot realistically achieve with conventional reconstructive techniques. Because immunosuppression to prevent rejection is such an onerous undertaking for the patient, VCA is currently restricted to major transplants. However, at some stage we will figure out a better and safer way to prevent rejection and then VCA will include transplantation of functioning eyelids, noses, ears, tongue and other specialized organs, all the areas that we currently can't effectively reconstruct with conventional techniques. While total nasal reconstruction, as an example, has attained a high level of sophistication, the truth is that elegant total nasal reconstructions are achieved by only a small number of expert surgeons utilizing very complex techniques in a series of operations over a period of months or years. The concept of a surgeon being able to transplant a nose in a single stage and achieve an elegant result is very attractive. The same is true for many other body parts, such as ears, tongue, genitalia, etc. In fact, penile transplantations have already become a reality. Obviously many obstacles remain before we will see this range of transplants in practice. VCA is a perfect example of how an innovative technical advance engenders increased research activity. The barrier to successful transplantation is not a technical one, it is an immunologic one and current interest in VCA has spawned a new wave of research activity in the field of immunology. This demands a collaborative and multidisciplinary approach, something that, again, plastic surgeons do well.

Collaboration

Plastic surgeons cannot lay claim to being the only innovators in medicine. Medicine is full of innovators. Yet it is true that the nature of the plastic surgeon's work, more than many other specialties, demands innovation. And that is what most plastic surgeons do every day of the week. Because so much of what we do, particularly in reconstructive surgery, is in collaboration with other specialties, innovation in those areas of practice often lead to innovations in our field. Most of the innovations we see are incremental. A surgeon incrementally changes how

Fig. 1.2 Dr. Paul Tessier. (Courtesy of Barry M Jones.)

(s)he practices or how (s)he does a particular operation. Every now and again the innovation is radical. The development of craniofacial surgery is an example of radical innovation. Paul Tessier (Fig. 1.2) was the first to describe a combined intra- and extracranial approach for the correction of hypertelorism,^{13,14} breaking the previously held taboo of exposing the intracranial environment to the upper aerodigestive tract. Going against the surgical mainstream demands unimaginable courage. It takes pioneers like Dr. Tessier to have the courage of their convictions, or the obstinacy to push the envelope beyond the general comfort level. Apart from spawning the specialty of craniofacial surgery, Dr. Tessier's advances led to advances in related fields. An interesting footnote is that we now rarely see cases of hypertelorbitism, presumably because they are detected in utero and the fetuses aborted.

One of the related fields that Dr. Tessier's work influenced is that of skull base surgery. The craniofacial principles developed by Dr. Tessier literally opened this field. Tumors that were previously considered inoperable and inaccessible became treatable. That progress led to further innovations. So, continuing with the example of skull base surgery, the radical resections and approaches that were developed in the 1970s and 80s^{15,16} created complications such as meningitis, brain abscesses and problems related to delayed wound healing. Smaller defects could be closed with local flaps such as pericranial flaps, or galeafrontalis flaps.¹⁷ However, larger defects remained a problem until free flaps were used to close these defects.^{18,19} Then the incidence of all of the complications, the brain abscesses, meningitis and wound healing problems, were dramatically reduced and the surgery became safer. So microvascular surgery made skull base tumor surgery safer. More recently in this field we have seen innovations in the surgical approaches to the skull base facilitate the development of endoscopic skull base surgery. Large resections are

Fig. 1.3 The Editor and Dr. Joe McCarthy at the launch of *Plastic Surgery*, 3rd edition.

now feasible through an endoscopic approach. This development has had a large impact on these patients because extensive open approaches, with the associated risks of scarring and deformity, are no longer necessary. However, with these large endoscopic resections, we are seeing the re-emergence of problems such as meningitis and abscess because of the difficulty in reconstructing these defects endoscopically.²⁰ This has led to the development of new reconstructive techniques and approaches in order to address these complications.^{21–23} This is an excellent example of how a multidisciplinary approach can advance a field. An innovation in one area can create a problem in another area that forces further innovation.

Similarly, an innovation in another specialty can change the way we practice in ours. An example is the introduction of bone lengthening procedures by Dr. Gavril Ilizarov.²⁴ This was revolutionary in the 1960s. That technology was adapted by Dr. Joseph McCarthy (Fig. 1.3) and applied to the craniofacial skeleton.^{25–27} This innovation has changed the way many craniofacial deformities are treated. Dr. McCarthy, incidentally, edited the first edition of *Plastic Surgery*.

Progress in surgery, regardless of specialty, demands a balance between innovators and conservatives. Innovators push the envelope and work best when they are paired with conservatives who rein them in to a degree. Thus, a balance between out-of-the-box thinking and conservative

deliberation is the perfect milieu to effect change yet keep perspective.

Drivers of innovation

As already mentioned, innovation is also forced in times of upheaval and change. The classic examples are war and natural disasters. More surgical advances are made in wartime than in peacetime. This is because specific problems are seen in unprecedented numbers and demand a solution. In this sort of environment it becomes reasonable to break the rules. One has to, simply, cope. Out of this generally comes a change in practice. Most of the advances in how we manage major trauma have come from the arena of war. The MASH units of the Korean conflict taught us that initiating treatment early, in the field, saves lives. The ultimate progression of that concept has been the development of robotic surgery, bringing high level expertise to the field so that skilled intervention can be effected at the earliest possible opportunity. The fact that this can be achieved using robotic technology makes it feasible for a highly skilled surgeon located in some central site to treat multiple injuries in separate locations.

The types of injury seen in war also lead to changes in practice. Plastic surgery, as we know it today, was born during the First World War. Sir Harold Gillies (Fig. 1.4) developed techniques for facial reconstruction initially at Aldershot and later at the Queen's Hospital in Sidcup, Kent. (It later became Queen Mary's Hospital.) His innovative solutions for some of the injuries he saw led to the development of modern plastic surgery. During the Second World War, the Plastic Surgery Unit at the Queen Victoria Hospital in East Grinstead, headed by Sir Archibald McIndoe (Gillies' cousin) (Fig. 1.5) became famous for treating severely burned airmen. This surgery was so experimental that McIndoe's patients formed a club known as the Guinea Pig Club. The club was initially formed as a drinking club and its membership was made up of injured airmen in the hospital as well as the surgeons and

Fig. 1.4 Sir Harold Gillies.

Fig. 1.5 Sir Archibald McIndoe. (Courtesy of Blond McIndoe Research Foundation, registered charity no. 1106240.)

anesthesiologists who treated them. Airmen had to have gone through a minimum of 10 surgical procedures before being eligible for membership in the club. By the end of the war the club had 649 members. The club itself was socially innovative because McIndoe conceived it as a way of integrating injured airmen back into society. He convinced some of the local families in East Grinstead to accept his patients as guests and other residents to treat them as normally as possible. It was very successful and East Grinstead became known as “the town that doesn’t stare”.

Innovation and development in other spheres has also changed the face of plastic surgery and brought further reconstructive challenges to surgeons. For example, the development of effective body armor has led to an increase in the types of injuries we see in the unprotected areas such as the limbs and the head and neck. It is not that these injuries didn’t occur before. It is simply that before the military had effective body armor, soldiers were dying of their injuries and we did not have to deal with their devastating facial or extremity injuries. Limb amputations are surprisingly common. In the US it is estimated that there are 10 000 new upper limb amputees every year. This has led to the development of innovative prosthetics as well as novel techniques to power these prosthetics. Use of myoelectric technology has led to innovations in the surgical approach to amputations and amputation stumps.^{24,25} It is likely that VCA (Ch. 32)) will change the reconstructive landscape for these devastating injuries and we are already seeing that in the upper limb.

Principles of innovation

I mentioned that innovations are based on principles. What are those principles and on what are they based? Obviously the specific principles will depend on the area under study. The principles on which innovation are based will be different for plastic surgeons as compared to gastrointestinal surgeons, for example. Central to everything and what I consider the core of plastic surgery is a detailed knowledge of anatomy. As

a specialty and in general, plastic surgeons have a more detailed knowledge of anatomy than any other specialty. Of course the cardiac surgeon knows the heart better than anyone and the orthopedist knows his bones better than anyone but neither of these specialties are likely to be in each other’s domain very often. Yet the plastic surgeon is frequently asked to cover exposed fractures or to provide vascularized cover for an infected sternotomy wound. Neither of these tasks is possible without a detailed knowledge of the anatomy of the region. Regardless of the area of subspecialty practice one is in, whether it is cosmetic surgery or hand surgery, a detailed knowledge of anatomy is the most important core understanding that is required to do the job well.

To drill down and define what is the single element of anatomic knowledge that is most vital to us, the answer would have to be vascular anatomy. Because so much of what we do involves the rearrangement of tissue, either locally, regionally or from afar, we have to know what keeps that tissue alive and we have to preserve that element. It is interesting to look at the advances that have been made in plastic surgery over the past 50 years. Many of them are directly related to a better knowledge of vascular anatomy. The most tangible of these is the development of flap surgery. We have come from an era when all flaps were random, to the present time when we know not only which blood vessel is supplying our flap but how much of that tissue is being perfused by that blood vessel. Innovations in imaging technology allow us the luxury of a roadmap to the vascular anatomy of our planned reconstruction using CT and/or MRI technology.^{26–28} Even better, we have a surgical GPS that allows us to visualize perfusion in real time using indocyanine green.²⁹ Technical advances allow us to transfer the tissue and perform a microvascular anastomosis to restore its blood supply. However it goes beyond that. We can also restore function, sometimes using microsurgical techniques, other times, once again, utilizing our knowledge of anatomy, by robbing Peter to pay Paul. Tendon transfers, for example, have long been a technique for restoring function to a compromised limb.^{30–32} More recently, nerve transfers have been utilized and are proving to be a valuable addition to our reconstructive armamentarium.³² These are all examples of innovation, describing a new solution to an otherwise insoluble problem.

We have also combined our knowledge of vascular anatomy with our knowledge of genetic engineering. Using genetic engineering we can program cells to perform certain tasks. We can suppress certain functions, stimulate others; in other words we can manipulate cells. This is a very powerful science and has potential applications across all of medicine. The process of transfection, whereby DNA or RNA is introduced into cells to modify gene expression, is widely used in molecular research. Geoff Gurtner, Editor of this volume of *Plastic Surgery* introduced us to the concept of “biologic brachytherapy”.³³ Using techniques of viral transfection, he has been able to design flaps that not only close a surgical defect but introduce a therapeutic element to the reconstruction by having the flap produce peptides appropriate to the disease entity being treated, producing probiotics for infected wounds, or antiangiogenic peptides for oncologic reconstructions. This innovative approach combines the best of plastic surgery with the best of genetic engineering to provide a new and better solution to an existing clinical problem. Biologic brachytherapy represents the melding of anatomic knowledge

Fig. 1.6 Dr. Wayne Morrison.

with tissue engineering principles and is a very exciting development.

The concept of flap prefabrication is another imaginative way of providing a better solution to a clinical problem.³⁴ Using these techniques, the most appropriate reconstructive construct can be assembled prior to the definitive reconstruction. While flap prefabrication is an elegant approach to a complex problem, it demands a high level of expertise, imagination and an innovative outlook. It also demands multiple stages and increased time to complete the reconstruction. In some disease states, such a delay may not be feasible. Engineering body parts is yet another approach that is currently being developed. Wayne Morrison (Fig. 1.6), working in the Bernard O'Brien Institute in Melbourne, has been able to grow functioning cardiac muscle³⁵ as well as functioning islet cells.³⁶ He continues to work on various matrix types to produce vascularized tissue chambers in which different cell types can be grown and vascularized. The ultimate aim is to produce clinically viable engineered organ parts.³⁷ This introduces the concept of “spare-parts” surgery, something that, while still not a reality, is no longer the stuff of science fiction.

The concept of making new tissue constructs is not new and is the basis, for example, of bone distraction and tissue expansion. Tissue expansion has been around since the 1980s. In fact, like many things in medicine, it was originally described long before that,³⁸ but was only popularized in the 1980s.³⁹ It has become one of the standard ways to reconstruct a breast following mastectomy and, of course, it has multiple other uses. When first introduced by Radovan, like many innovations, it was considered with a great deal of skepticism. Unfortunately Radovan did not live to see his idea become widely accepted.

Innovation also involves the application of established techniques in new areas. Bone distraction is an example that was cited already. Devised by Ilizarov for the treatment of long bones, the technique has been adapted to the craniofacial skeleton. The applications of bone distraction in plastic surgery are more recent. Popularized by McCarthy,⁴⁰ bone distraction has changed the practice of craniofacial surgery, minimizing the extent of surgery required to treat certain conditions while improving outcomes. Such developments occur all the time and sometimes there is a disconnect between the development of the original idea and its ultimate application. An example of this is the Brava bra. This was first developed as a means of achieving breast augmentation non-surgically.⁴¹ Applying a

vacuum to the breast caused swelling and enlargement. This was somewhat of a transitory enlargement but, nevertheless, an enlargement. Several other innovations led to a rethinking of what was happening with the Brava system and ultimately led to a very innovative approach to breast reconstruction that is still in the initial stage of skeptical interest but that may well become an established technique. This association of ideas is often how innovation works. What were these different ideas? Each in its own right is a major innovation.

The first is fat grafting. This is an old idea and one with a checkered history. Dermal fat grafts have long been an accepted method of correcting small contour defects. Attempts at engrafting larger fat deposits have generally been unsuccessful. The concept of fat injection as a means of engrafting fat is another idea that was greeted with skepticism until Coleman and others showed us that it does work when the fat is deposited in small aliquots with a fine cannula.^{37,42,43} This technique is now widely practiced in both aesthetic and reconstructive arenas and has become an invaluable addition to our armamentarium.

The second innovation is tissue expansion. Though tissue expansion has been around for a long time, we have thought of it in terms of internal expansion, i.e. expansion produced by the implantation of an expanding device. The suction system used by the Brava bra introduces us to the concept of external expansion, i.e. expansion caused by external forces, the application of a vacuum to the skin.

The third innovation is that of vacuum-assisted closure, the VAC system. This is an idea so simple that we all wish we had thought of it. However, as with many things in medicine, it is not as simple as it first appears. Not only, it appears, does the VAC mechanically remove debris and exudate from the wound, but it also promotes angiogenesis and cell proliferation.^{44–46}

Putting all these concepts together, Khouri has developed a system for both breast reconstruction as well as breast augmentation, which uses the Brava system, married to the structural fat-grafting concept, whereby the external expansion induced by the Brava vacuum produces edema, angiogenesis and cell proliferation that permits larger volumes of fat to be deposited in a favorable matrix, thereby increasing graft take and fat retention. To date, the results of this approach are remarkable. Undoubtedly there are many unanswered questions and here, once again, we have an example of an innovation that has already found clinical application but that requires extensive research to elucidate the mechanism of the clinical picture we are seeing.

Fat grafting, as well as providing a clinical solution to many problems, both aesthetic and reconstructive, has also engaged our curiosity in another area – that of stem cell research. This again represents an association of ideas from disparate fields. Many of the changes we see as a result of fat grafting are not readily explained by the injection of fat alone. As an example, it has been reported that many of the skin changes associated with irradiation seem to be reversed when fat is injected into, for example, a breast defect resulting from lumpectomy and irradiation.⁴⁷ Why should this be? The answer, stem cells, may be a simplistic solution to explain something we don't understand. The answer may also be our introduction into a whole new area of development for plastic surgery. Of course, as we've seen before, not only does this innovation (fat grafting) solve a clinical problem, it raises

numerous questions and opens the door to new areas of research and quite likely to even newer innovations.

External influences and innovation

In order to achieve some of our surgical results we rely not only on our own expertise as surgeons, we also rely on our tools, our instruments and devices. Microsurgery could not have developed without the development of the operating microscope and appropriate instrumentation. One of the biggest barriers to the development of modern microsurgery was the inability to swage an ultrafine suture to a sufficiently small needle. Similarly, the manufacture of implants of any kind demand an expertise that we, as surgeons, do not have. Bioengineers, chemists, physicists and all manner of experts are required to help bring our ideas into clinical practice. None of these developments are possible without the partnership of industry. Of course this is a double-edged sword as it introduces other interests and possible conflicts. Nevertheless, it is a vital part of the development of any specialty.

I've already mentioned how microsuture development led to the development of reconstructive microsurgery. Once it was possible to do microanastomoses, it became possible to replant amputated digits. The new technology spurred the advance of flap surgery and our interest in vascular anatomy was again renewed. This inspired the likes of Mathes and Nahai to elucidate and classify the blood supply of muscles and others to describe new myocutaneous flaps. Ian Taylor started his classic cadaver injection studies that led to the development of the angiosome theory. Later, Isao Koshima and others described perforator flaps and that development and innovation is ongoing.

Craniofacial surgery is another subspecialty area that could not have developed without the help of industry. When Joseph Gruss recognized the importance of internal fixation for the craniofacial skeleton in the early 1980s he was using wires to painstakingly piece together comminuted fractures. This led him and others to the recognition of the concept of facial buttresses and to the development of plating systems for the face. This approach is now standard of care but could not have happened without the expertise of the engineers and implant biologists who worked with surgeons to develop the plating systems and instrumentation that make it all possible. Once again, this is an ongoing process.

Every aspect of plastic surgery has undergone such change and development. In cosmetic surgery we have also seen these changes evolve. In each area, surgeons have developed a better understanding of anatomy and function and developed, with industry, ways to improve and develop the field. Endoscopic techniques were adapted from other areas of practice and applied to the face, and minimally invasive techniques led to the development of barbed sutures and suspension systems. Implant biology has brought us various injectable fillers and broadened the scope of cosmetic surgery in a way that was once unimaginable.

So innovation is a natural consequence of practice. In every sphere people strive to improve things, surgeons to do better operations, anesthesiologists to improve pain control, industry to provide better materials and instruments. These innovations occur in all specialties and, as we have seen, innovation in one specialty can influence how another develops. What

about innovation itself? How can we ensure that innovation is as safe as possible and conducted in some sort of organized fashion and with some form of structure? Do we need such organization and such structure? As I mentioned at the outset, a discussion on the ethics of innovation is beyond the scope of this chapter. However, there are some things that are useful to consider.

Documentation, data gathering and regulation

It is important to document change. If one asks a surgeon how many procedures (s)he has done, the answer is usually a gross exaggeration. Similarly we tend to underestimate our complications. We're not good at remembering stuff though we think we are. It is surprising when one starts to keep a database how sobering it is to see the actual numbers. It's also surprising how much information one can glean and this information is vital if we are to change and improve. Innovation implies change and in times of change it is imperative to document results. How else can one evaluate the effects of the innovation? So documentation and data gathering are important aspects of innovation.

The difficulty with innovation arises in that gray zone between innovation and research. Small changes are easy to effect, large changes more difficult! Most institutions regulate change through the institutional review board (IRB). Regulation is necessary yet it is also restrictive. The IRB process varies from institution to institution but, in general, is getting more and more stringent. This can have a significant effect on the development of medicine as a whole. It is widely believed, for example, that the reason the first heart transplant did not occur in the United States was because of the stringent regulations governing experimental surgery in the US as compared to South Africa where Dr. Christiaan Barnard, an American-trained cardiac surgeon, performed this operation. Institutions also grapple with the dilemma of allowing some degree of innovation, yet controlling quality and risk exposure. The latter is an important consideration for institutions and individuals alike. Apart from protecting the individual and the institution, regulation also introduces and enforces an element of objectivity. When one is involved in developing a theory, an operation, or some sort of change, it is very easy to lose objectivity and that is a serious issue. Regulation enforces objectivity and the difficulty lies in the balance between creativity and objectivity. Just as one can become obsessed with creativity and freedom of expression, however, one can also become obsessed with objectivity and regulation. Finding a balance between the two is sometimes difficult. Added to that is the conflict of interest that is sometimes introduced to the process when a commercial value is associated with the innovation, and particularly when a significant sum may already have been invested in developing it. That introduces the ethics of practice and this subject is covered in Chapter 4.

So we have seen that innovation is an important part of medicine. It is separate from research though often stimulates research. It is as difficult to regulate as it is to define and, at least in some instances, may be stifled by regulation. From all of the innovations I have touched on in this chapter we can see that innovation is vital to the development of medicine in general and to the evolution of plastic surgery in particular.

Flap prefabrication in the head and neck: a 10-year experience. *Plast Reconstr Surg*. 1999;103:808–820. *Tissue neovascularized by implanting a vascular pedicle can be transferred as a "prefabricated flap" based on the blood flow through the implanted pedicle. This technique potentially allows any defined tissue volume to be transferred to any specified recipient site, greatly expanding the armamentarium of reconstructive options. During the past 10 years, 17 flaps were prefabricated and 15 flaps were transferred successfully in 12 patients. Tissue expanders were used as an aid in 11 flaps. Seven flaps were prefabricated at a distant site and later transferred using microsurgical techniques. Ten flaps were prefabricated near the recipient site by either transposition of a local vascular pedicle or the microvascular transfer of a distant vascular pedicle. The prefabricated flaps were subsequently transferred as island pedicle flaps. These local vascular pedicles can be re-used to transfer additional neovascularized tissues. Common pedicles used for neovascularization included the descending branch of the lateral femoral circumflex, superficial temporal, radial, and thoracodorsal pedicles. Most flaps developed transient venous congestion that resolved in 36 to 48 hours. Venous congestion could be reduced by incorporating a native superficial vein into the design of the flap or by extending the prefabrication time from 6 weeks to several months. Placing a Gore-Tex sleeve around the proximal pedicle allowed for much easier pedicle dissection at the time of transfer. Prefabricated flaps allow the transfer of moderate-sized units of thin tissue to recipient sites throughout the body. They have been particularly useful in patients recovering from extensive burn injury on whom thin donor sites are limited.*

Flap prefabrication in the head and neck: a 10-year experience. *Plast Reconstr Surg*. 1999;103:808–820. *Tissue neovascularized by implanting a vascular pedicle can be transferred as a "prefabricated flap" based on the blood flow through the implanted pedicle. This technique potentially allows any defined tissue volume to be transferred to any specified recipient site, greatly expanding the armamentarium of reconstructive options. During the past 10 years, 17 flaps were prefabricated and 15 flaps were transferred successfully in 12 patients. Tissue expanders were used as an aid in 11 flaps. Seven flaps were prefabricated at a distant site and later transferred using microsurgical techniques. Ten flaps were prefabricated near the recipient site by either transposition of a local vascular pedicle or the microvascular transfer of a distant vascular pedicle. The prefabricated flaps were subsequently transferred as island pedicle flaps. These local vascular pedicles can be re-used to transfer additional neovascularized tissues. Common pedicles used for neovascularization included the descending branch of the lateral femoral circumflex, superficial temporal, radial, and thoracodorsal pedicles. Most flaps developed transient venous congestion that resolved in 36 to 48 hours. Venous congestion could be reduced by incorporating a native superficial vein into the design of the flap or by extending the prefabrication time from 6 weeks to several months. Placing a Gore-Tex sleeve around the proximal pedicle allowed for much easier pedicle dissection at the time of transfer. Prefabricated flaps allow the transfer of moderate-sized units of thin tissue to recipient sites throughout the body. They have been particularly useful in patients*

recovering from extensive burn injury on whom thin donor sites are limited.

Clinical treatment of radiotherapy tissue damage by lipoaspirate transplant: a healing process mediated by adipose-derived adult stem cells. *Plast Reconstr Surg.* 2007;119:1409–1422, discussion 1423–1424. *There has been a lot of discussion about the contribution of stem cells to restoration of tissue vascularization and organ function. This study aimed to assess the presence of adipose derived stem cells which were in the lipo-aspirate and to assess the clinical effectiveness of lipoaspirate transplantation in the treatment of radiation induced tissue injury. The authors followed 22 patients with significant radiation effects for 31 months after lipoaspirate injection. Clinical outcomes led to an improvement of symptoms and they concluded that this is a low invasive therapeutic approach for resolving the late side effects of radiotherapy.*

History of reconstructive and aesthetic surgery

Riccardo F. Mazzola and Isabella C. Mazzola

SYNOPSIS

- Closure of wounds represents one of the first gestures of reparative surgery.
- History shows that almost every possible local flap has been described in the past and that the ingenuity of plastic surgeons was unlimited.
- The lesson drawn from history reveals that the so-called new flaps are variations of what has already been published.
- We have to be humble and recognize that “nothing is new under the sun.”

Historical definition of plastic surgery

In 1597, the Bolognese Gaspare Tagliacozzi (1545–1597), considered the founder of plastic surgery, gave the following definition of our discipline: plastic surgery is the art devoted to “restore what Nature has given and chance has taken away. The main purpose of this procedure is not the restoration of the original beauty of the face, but rather the rehabilitation of the part in question”,¹ in other terms repair of congenital or acquired defects, restoration of an appearance as close as possible to normality, but also improvement of functional impairment. The term “plastic” comes from the Greek πλαστικός (*plasticós*), moldable.

Origin of plastic surgery

The distant past – the wound as a problem

The ancient origin of plastic surgery relates to the healing of wounds. Management of wounds caused by stones, weapons, arrows, and animal bites goes back millions of years, when primitive humans had to face four major problems: (1) closing posttraumatic defects; (2) bleeding; (3) infection; and (4) pain. Attempts to transform a defect that heals slowly by secondary

intention into one healing quicker by primary intention may well account for the first example of a reparative procedure.

However, this must have been quite complex without appropriate tools, in the presence of hemorrhage and without anesthesia. There is no documentation of stitching of wounds among primitive people.² We may extrapolate from what was reported in ancient Hindu medicine, where wound edges were sewn with simple means like fibers or strips of tendon, or pinned together using insect mandibles. Later, bronze pins were used (Fig. 2.1).

In Ancient Egypt

We are well informed about Egyptian surgery thanks to the Edwin Smith papyrus, the most ancient medical text. The papyrus is a later transcription (about 1650 BC) of an original manuscript dating from the Old Kingdom (between 3000 and 2500 BC). It describes 48 surgical cases, including wounds, fractures, dislocations, sores, and tumors, and suggests their potential management. Fresh wounds were treated conservatively with the application of grease and honey using linen and swabs. Adhesive strips of cloth, stitches or a combination of clamp and stitches were advocated to bring together the margins of the wound. A surgical knife was never mentioned, as wounds already existed in the cases presented.² Treatment of nasal fractures is accurately explained. First, clots should be removed from the inside of the nostrils, then the bony fragments repositioned; two stiff rolls of linen were applied externally “by which the nose is held fast” and finally “two plugs of linen saturated with grease placed into the nostrils.”³

In Mesopotamia

Mesopotamia is the region between the rivers Tigris and Euphrates (now approximately Iraq), cradle of the Sumerian civilization. Medicine was well developed, although strongly influenced by astrology and divination. During excavations of the Nineveh palace, a great library containing more than

Fig. 2.1 Bronze pin to approximate wound margins. (Reproduced from Rodius J. De Acia Dissertatio. Padua: Frambotto; 1639.)

30 000 clay tablets with cuneiform inscriptions was discovered, 800 of them of a medical nature. They were written about 600 BC, although the text dates from around 2000 BC. A few of them deal with wound healing or congenital anomalies. "If a man is sick with a blow on the cheek, pound together turpentine, tamarisk, daisy, flour of Inninnu [...] mix in milk and beer in a small copper pan; spread on skin and he shall recover."⁴ Another tablet suggests the use of a dressing with oil for an open wound.

Monsters (congenital malformations) had a key role in predicting future events and in determining their course. "When a woman gives birth to an infant [...] whose nostrils are absent, the country will be in affliction, and the house of the man ruined; that has no tongue the house of the man will be ruined; that has no lips affliction will strike the land and the house of the man will be destroyed."⁵ Interestingly, surgery is never mentioned in clay tablets, although surgery was certainly performed. In the King Hammurabi Code,² dating from about 1700 BC, surgical malpractice was recognized with precise laws: "If a physician carried out a major operation on a seignior with a bronze lancet and has caused the seignior's death or he opened the eye socket of a seignior and has destroyed the seignior eye, they shall cut off his hand." "If a physician carried out a major operation on a commoner's slave with a bronze lancet and has caused [his] death, he shall make good slave for slave."

In India

In the Samhita, a Sanskrit text on surgery attributed to Sushruta and possibly dating 600 BC, the description of several reconstructive procedures related to the face are discussed. In particular, management of eyelid anomalies like entropion, trichiasis, or ingrown eyelashes and repair of the nose is reported. Certain Indian populations had the habit of cutting the nose of adulterers, thieves and prisoners of war as a sign of humiliation. In an attempt to improve this terrible disfigurement, surgeons invented different solutions over the centuries.

Repair of the nose was carried out by the Koomas, a low caste of priests, or, according to others, a guild of potters. Local flaps, outlined in the cheek, were used, and accurate description of blunt (*yantra*) and sharp (*sastra*) instruments to perform nasal reconstruction was supplied.⁶

When was the forehead skin used? There is no mention of it. In the second half of the 17th century, the Venetian

adventurer Nicolò Manuzzi (1639–1717) wrote a manuscript about the Moghul empire in which an account of forehead rhinoplasty is supplied. Regrettably the manuscript, kept in the Marciana Library in Venice, was not published until 1907.⁷ Information on the forehead flap in nasal reconstruction only reached the western world at the end of the 18th century, thanks to a letter signed BL, addressed to Mr. Urban, editor of the *Gentleman's Magazine*, and published in October 1794 (Fig. 2.2).⁸

A friend of mine has transmitted to me, from the East Indies, the following very curious and, in Europe, I believe unknown surgical operation, which has long been practiced in India with success; namely, affixing a new nose on a man's face.

There follows the accurate description of the two-step procedure carried out on Cowasjee, a bullock driver of the English

Fig. 2.2 Indian forehead flap nasal reconstruction. (Reproduced from BL. Letter to the editor. *Gentleman's Magazine*. 1794;64:891–892.)

army, who fell under the disfavor of Tippoo Sultan, and had his nose amputated. It demonstrated the high level of surgery reached by the Indians in performing an operation, without anesthesia, in a very similar way to what we do nowadays.

In Greece

Greek medicine was influenced by Hippocrates, the greatest physician of his time. Historians consider that Hippocrates was born in the island of Kos around the year 460 BC, and probably trained in medicine at the Asklepieion of Kos. In ancient Greece and Rome, the Asklepieion (Latin: *aesculapīum*) was a healing temple, sacred to Asklepios, the Greek god of medicine. Hippocrates rejected the views of his time that illness was due to supernatural influence, possession of evil spirits, or disfavor of the gods. He based his medical practice on the direct observation of disease and on an analysis of the human body, introducing scientific methods into medicine. Hippocrates taught and practiced medicine throughout his life, traveling in various Greek regions. He established the Great School of Medicine on the isle of Kos. He probably died in Larissa (Greece) at the age of 83 or 90.

About 70 medical treatises, assembled during the Alexandrian era (third century AD), were attributed to Hippocrates. They form the so-called *Corpus Hippocraticum*. Whether Hippocrates himself is the author of the *Corpus* and these works are authentic has been the matter of great dispute and controversy.⁹ The *Corpus* contains manuals, lectures, research, philosophical thoughts, and essays on different topics of medicine, without any logical order and even with significant contradictions among them. The works of Hippocrates were true best-sellers, reprinted numerous times over the centuries. The first printed edition of the *Opera omnia* (Complete Works) was issued in Latin in Rome in 1525, and in Greek in Venice in 1526 by the Aldine Press.

The surgical knowledge of Hippocrates was vast. He used cauterization for the management of raw surfaces, reduced malunited fractures, and practiced cranial trephination to evacuate hematomas.

In Rome

In Rome, surgery was well developed, at least judging from the rather sophisticated bronze instruments discovered in Pompei and now kept at Naples National Museum. Many were stored in traveling kits to be used by surgeons for emergency or in the battlefields.

The two most representative figures of Roman medicine were Celsus and Galen.

Aulus Cornelius Celsus (25 BC–50 AD) was probably not a physician, but a writer from a noble family and the author, in about 30 AD, of *De Medicina* (On Medicine) in eight volumes. In book seven, chapter nine, vessel ligation and lithotomy as well as lip closure (cleft lip or lip tumor) by means of flaps are reported. It is explained how “defects of the ears, lips and nose can be cured” (*curta in auribus, labrisque ac naribus, quomodo sarciri et curare possint*), followed by a description of wound closure by advancement flap.¹⁰ “The defect should be converted into a square (*in quadratum redigere*). Then, from the inner angles transverse incisions are made (*lineas transversas incidere*), so that the part on one side is fully divided from that on the opposite side.” “After that, the tissues which have been

Fig. 2.3 Lip repair according to Celsus. (Reproduced from Nélaton C, Ombredanne L. *Les Autoplasties*. Paris: Steinheil; 1907.)

undermined, are brought together” (*in unum adducere*). “If this is not possible two additional semilunar incisions are made at some distance from the original (*ultra lineas, quas ante fecimus, alias duas lunatas et ad piagam conversas immittere*), but only sectioning the outer skin. [...] These latter incisions enable the parts to be easily brought together without using any traction” (Fig. 2.3). Celsus holds a key role in the history of plastic surgery, as he is considered the earliest writer on this particular topic. He introduced the four cardinal signs of acute inflammation, “redness and swelling with heat and pain” (*rubor et tumor, cum calore et dolore*). A copy of Celsus’s manuscript was discovered in Milan in 1443, and printed for the first time in 1478 in Florence.¹¹ *De Medicina* went through more than 50 editions.

Claudius Galen (c. 129–201 AD) was born in Pergamon (Turkey), studied medicine at the Asklepieion (see above) in his native city and moved to Rome. He wrote about head traumas, techniques of trephination for evacuating hematomas and various types of bandaging. An excellent anatomist, he described more than 300 muscles, the seven pairs of cranial nerves and contributed to neurology, demonstrating that nerves arise from the brain or spinal cord. He observed that section of the laryngeal nerve resulted in dysphonia. For management of wounds he used sutures and cautery. Numerous works of Galen were lost, but 82 survived. Originally written in Greek, many were translated into Arabic and Latin. Galen’s *Opera* was first printed in Latin in Venice in 1490 and in Greek in Venice in 1525 by the Aldine Press.

Plastic surgery after the decline of the Roman Empire

Byzantine surgery

Oribasius (325–403 AD) wrote a collection of medical texts entitled *Synagogae Medicae* in which reconstructive procedures for cheek, nose, ears, and eyebrow defects are described.¹²

Paulus of Aegina (625–690 AD), surgeon and obstetrician, was the author of a medical encyclopedia (*Epitome*) in seven volumes. In book 6, which deals with surgery, a description of tracheotomy, tonsillectomy, ectropion, upper eyelid retraction and lip repair is supplied.^{13,14} “Defects [Greek, *colobomata*] of the lips and ears are treated in this way. First the skin is freed on the underside. Then the edges of the wound are brought together and the callosity is removed. Finally, stitches holding the margins into position are applied.” This technique closely resembles that of Celsus.

The Middle Ages

Arabian surgery

Arabian medical writers came from different nations, such as Persia, Syria, and Spain. Their only common denominator was the language. The most representative figure was Abū-l-Qāsim or Albucasis (c. 936–1013 AD), whose famous treatise, *Al Tasrif* (*On Surgery*), was translated into Latin and first published in 1500. It included more than 200 illustrations of surgical instruments, such as tongue depressor, tooth extractor, hooks, and cauteries, most invented by Albucasis himself, with an explanation of their use.¹⁵ Like most Arabian surgeons, Albucasis was a proponent of cautery, for different clinical applications and the management of wounds and cleft lip. He was the first to use a syringe with a piston.

The rise of the universities

The founding of the universities is one of the most important events in the Middle Age and a key factor in the development of modern culture. Originally, *universitas* denoted an aggregation of masters (*magistri*), students, or both, and the primary goal was teaching philosophy and theology. Lessons were practiced in the house of the masters or in small rooms. Students sat on the floor, whereas the professor was in the chair. The oldest university, at least in Europe, was Bologna, established in 1088, followed by Paris, Oxford, and Montpellier. In Bologna medicine was taught and cadaver dissection was accepted, thus significantly contributing to the development of the study of anatomy. Mondino de’ Luzzi (1270–1326) was the first anatomist to lecture directly in front of the cadaver (Fig. 2.4). As anatomists were also surgeons, such as Henry of Mondeville (1260–1320) or Guy of Chauliac (1300–1368), surgery was part of the teaching program of anatomy.

The discovery of printing

The invention of printing around 1440 by Gutenberg spread medical knowledge and considerably enlarged the libraries of universities and monasteries.

The first printed textbook on surgery was *La Ciroxia* (*On Surgery*), by William of Saliceto (1210–1277), issued in Venice in 1474. This text has particular relevance in the history of surgery, because it reintroduced the use of the surgical knife to replace cautery, strongly advocated by Arabian surgeons. The first printed textbook on anatomy was *Anatomia* by Mondino de’ Luzzi, issued in Padua about 1476, which remained the reference text for numerous years. The printed works of Hippocrates, Galen, Celsus and Arabian writers played a key role in educating medical students.

Fig. 2.4 Mondino in the chair supervising a cadaver dissection. (Reproduced from Ketham J. Fasciculus de Medicina. Venice: Gregorio de’ Gregorii; 1493.)

The Renaissance

Renaissance surgery

The most celebrated surgeon of the Renaissance was the Frenchman Ambroise Paré (1510–1590) (Fig. 2.5). A humble but very talented barber-surgeon, Paré amassed considerable experience from his tireless work in the battlefields. At that time, gunshot wounds were considered poisoned and barbarically cauterized either with red-hot iron, or with boiling oil poured directly into the wound. On the contrary, Paré used simple dressings and soothing ointment made of egg yolk, oil of roses and turpentine with great benefit for the soldiers. The conclusion was that less invasive methods were far superior to the traditional ones. In 1545 he published his observation in *La Méthode de traicter les playes...* (*The Method of Treating Wounds...*). Paré’s works were collected in a single folio volume, “*Les Oeuvres*”, first published at Paris in 1575 and dedicated to Henry II, King of France.¹⁶ Paré’s contributions to plastic surgery were significant. He showed the first image of a cleft lip suture in medical literature (Fig. 2.6). To facilitate healing avoiding potential wound breakdown and reducing the risk of unpleasant wide scar formation on the face, he applied adhesive and fastened the wound margins (Fig. 2.7).

Fig. 2.5 Portrait of Ambroise Paré (1510–1590).

He described and illustrated a vast number of congenital malformations, some real and others the result of fantasy, the so-called monstrosities.

The year 1583 marks a great breakthrough in ophthalmology and eyelid surgery with "*Ophthalmodouleia, das ist Augendienst*" (Ophthalmodouleia, or the Service of the Eyes) by Georg Bartisch (1535–1607), oculist to the Elector August of Saxony.¹⁷ The book constitutes the first comprehensive treatise on the care and management of the diseases of eye and adnexa and is embellished by dozens of detailed anatomical images of the eye, eyelids and brain, as well as of surgical instruments. Besides this, it includes the first clinical illustration of blepharochalasis and baggy eyelid (Fig. 2.8) and the report of an original technique for surgical excision of the overhanging skin fold above the tarsus for correcting blepharochalasis, using a curved clamp in the form of a guillotine (Fig. 2.9).

The beginning of plastic surgery is usually associated with *De Curtorum Chirurgia per Insitionem* (On the Surgery of Injuries by Grafting),¹⁸ published in Venice in 1597, by Gaspare Tagliacozzi (1544–1599), Professor of Surgery at Bologna University, in which the procedure for nasal reconstruction is shown step by step and skillfully illustrated. The instruments necessary for the operation are presented first, followed by the indications, flap outlining on the arm, flap inset, the bandage necessary to secure the arm into position, resection of the vascular pedicle, final result, as well as the different clinical

applications of the technique for lip and ear defects (Fig. 2.10). The book was well received and reprinted in a pocket edition at Frankfurt the following year, directed specifically at military surgeons who were often confronted with the problems of nasal repair in the battlefields.

But when did nasal reconstruction start in the western world and from whom did Tagliacozzi learn the technique?

The operation was performed by members of the Branca family from Catania (Sicily). Gustavo (early 15th century) used skin taken from the cheek. His son, Antonio, made considerable improvements to the operation. He selected the arm as the donor site, to avoid further scars on the face. About 1460, at Antonio's death, the Branca method, which was kept as a family secret and passed on by word of mouth, was discontinued in Sicily. It was resumed by Vincenzo Vianeo in Calabria (southern Italy). His sons Pietro (about 1510–1571) and Paolo (about 1505–1560) established a flourishing clinic for rhinoplasty in Tropea (Calabria). Evidence of their reconstructive work comes from the Bolognese army surgeon Leonardo Fioravanti (1517–1588), who assisted in Vianeo's operations and issued a detailed report in *Il Tesoro della Vita Humana* (Treasure of Human Life) issued in Venice in 1570.¹⁹

I moved to Tropea where at that time there were two brothers Pietro and Paolo, who made a nose for anyone who had lost his by some accident [...]. I went every day to the house of these

Fig. 2.6 Cleft lip repair. (Reproduced from Paré A. *Les Oeuvres*. Paris: Buon; 1575.)

Fig. 2.7 Facial wound suture. A piece of linen is stitched to the skin to facilitate wound edge approximation. (Reproduced from Paré A. *Les Oeuvres*. Paris: Buon; 1575.)

surgeons, who had five noses scheduled for repair and when they wanted to perform these operations they called me to watch and I, pretending I had not the courage to look at, I turned my face away, yet my eyes saw perfectly. Thus, I observed the whole secret from top to toe, and learned it.

Then follows the description of the arm flap procedure.

Possibly Fioravanti's book came to the attention of Gaspare Tagliacozzi who successfully applied the technique on some patients and published his famous textbook in 1597. Although Tagliacozzi was not the discoverer of rhinoplasty, and the arm flap operation is now rarely performed, he deserves credit for being the first to make a work of art out of a surgical practice, for systematizing and promulgating nasal reconstruction. He is rightly considered the founder of plastic surgery.

Fig. 2.8 Blepharochalasis and baggy eyelids. (Reproduced from Bartisch G. *Ophthalmoduleia, das is Augendienst*. Dresden: Stöckel; 1583)

The decline of plastic surgery

After Tagliacozzi's death, apart from his pupil G. B. Cortesi (1554–1634), who published a book on nasal reconstruction in 1625,²⁰ the operation, which was difficult to perform, became obsolete for almost two centuries. Sporadic cases were

Fig. 2.9 First illustration of blepharochalasis correction. (Reproduced from Bartisch G. *Ophthalmoduleia, das is Augendienst*. Dresden: Stöckel; 1583)

Fig. 2.10 Nasal reconstruction with the arm flap. **(A)** Preoperative view of the patient. The missing nose and flap are outlined. **(B)** The flap sutured into position. **(C)** Final result. (Reproduced from Tagliacozzi G. *De Curtorum Chirurgia per Insitionem*. Venice: Bindoni; 1597.)

reported in 17th- or 18th-century literature. Instead of recommending autologous tissue for restoring a missing nose, surgeons like Fallopio (1523–1562), Heister (1683–1758), Camper (1722–1789), and others advocated the application of a prosthesis, convinced that noses made out of wood or silver were far superior to those of skin.

The rebirth of plastic surgery

The 1794 letter to the editor of the *Gentleman's Magazine* (see above) holds a key position in the revival of plastic surgery. The English surgeon Joseph Constantine Carpue (1764–1846) read it and made practical and successful use of its contents. In 1814, he carried out the first forehead flap rhinoplasty of modern time at St. Bartholomew's Hospital, London, on an officer of His Majesty's Army, who had his nose amputated during a battle. The operation lasted 35 minutes, "it was no child's play, extremely painful – the officer said – but it was no use complaining." At the end he exclaimed: "my God, there is a nose!"

In 1816, Carpue issued an account of nasal reconstruction, which marks the prelude to the rebirth of modern plastic surgery (Fig. 2.11).²¹

The 19th century

The golden age of plastic surgery

Carpue's work was immediately translated into German, and Carl Ferdinand von Gräfe (1787–1840), Professor of Surgery at Berlin University, promptly initiated the operation. In 1818,

he published *Rhinoplastik oder die Kunst den Verlust der Nase organisch zu ersetzen* (*Rhinoplasty: or the Art of Reconstructing the Nose*), where he compared the Italian and Indian procedures.²² Von Gräfe supported the arm flap, as he was unhappy about forehead donor site scar morbidity.

The publications of Carpue and von Gräfe stimulated the interest of European surgeons to carry out nasal and other reconstructions. In Germany, Johann F. Dieffenbach (1794–1847), head of surgery at La Charité Hospital in Berlin, performed rhinoplasty, facial restorations, cleft lip and palate repairs. He reported his contributions in *Chirurgische Erfahrungen* (*Surgical Experiences*), issued in 1829.²³ In France, Jacques Mathieu Delpach (1777–1832), chief surgeon at Montpellier, wrote *Chirurgie Clinique de Montpellier* in 1828, with a detailed section on rhinoplasty.²⁴ Outstanding works on the rediscovered art were presented by Pancoast (1805–1882)²⁵ in the US, Balassa (1814–1868)²⁶ in Hungary, and Sabattini (1810–1864)²⁷ in Italy. A review of the state of the art of nasal reconstruction in Europe in the mid 19th century was published by Nélaton and Ombredanne in 1904,²⁸ and more recently by McDowell,²⁹ Rogers,³⁰ and Mazzola.³¹

With the advent of anesthesia (1846) and the possibility of closing the donor site primarily, leaving a scar that was often unnoticeable, forehead rhinoplasty became the procedure of choice due to its simplicity, good color match, and excellent results.

The first attempt to close a cleft palate goes back to the second decade of the 19th century. The priority is shared between Carl Ferdinand von Gräfe³² and Philibert Roux (1780–1854) from France.³³ However, the greatest advance was made in 1862 by Bernard von Langenbeck (1810–1887), who outlined two mucoperichondrial flaps obtaining a more reliable closure.³⁴ Refinements in cleft lip repair were published

An Account of Two Successful Operations for Restoring a Lost Nose from the Integuments of the Forehead, in the Case of Two Officers of his Majesty's Army. London: Longman, Hurst; 1816.)

by the Frenchmen Joseph Malgaigne (1806–1865)³⁵ and Germanicus Mirault (1796–1879) in 1844.³⁶

Reconstructive procedures for lip³⁷ were reported by Pietro Sabattini in 1838, using the lip switch technique^{27,38} (Fig. 2.12), and by Victor von Bruns (1812–1883) in 1857, using double lateral flaps for oral sphincter restoration³⁹ (Fig. 2.13), whereas eyelid repair was reported by Johann Fricke (1790–1841) in 1829, who described a pedicled skin flap from the ipsilateral temple or cheek region to correct upper or lower eyelid defects, respectively⁴⁰ (Fig. 2.14).

One of the greatest advances in 19th-century surgery was the demonstration that a piece of skin, fully separated from its original site, might survive when transplanted to another part of the body to cover a granulating raw surface.⁴¹ This

became possible through the pioneering work of Giuseppe Baronio (1758–1811) from Milan, who performed the first autologous skin graft in a ram in 1804 (Fig. 2.15).^{42,43} Sixty-five years later, Jacques Reverdin (1842–1929) carried out the first successful epidermic graft on a human being at Hôpital Necker in Paris, opening a new era in wound-healing management.⁴⁴ The route for skin grafting was traced. A few years later, Louis Ollier (1830–1900) transferred a large piece of split-thickness skin, which included the superficial layers and underlying dermis.⁴⁵ Carl Thiersch (1822–1895)⁴⁶ and John R Wolfe (1824–1904)⁴⁷ made further advances in the procedure. In the late 1800s, skin grafting became the preferred solution for the management of chronic and granulating wounds.

The 20th century

The origin of modern plastic surgery

Trenches played an important role during World War I. Created for shielding purposes, they actually only protected soldiers' lower body and trunk, whereas the head and neck remained exposed to enemy weapons. As they returned home, soldiers with major maxillofacial mutilations found it impossible to step back into society, and this constituted a new social problem. Treatment of these devastating facial wounds urged the development of a new discipline, reconstructive surgery. The first plastic surgeons came from general surgery, otolaryngology, or orthopedics during the first two decades of the 20th century.

Fig. 2.15 First autologous skin graft in a ram. (Reproduced from Baronio G. *Degli innesti Animali*. Milan: Stamperia del Genio; 1804.)

Associations were created all over the world to help these poor individuals. The most famous was *Les gueules cassées* (The Facial Cripples), founded in France in 1921, by Colonel Picot. In addition to these associations, France, the UK, Germany, Italy, and Czechoslovakia established specialized centers to manage injuries that had never been seen before. The key to success was the cooperation between plastic surgeons, trained in soft-tissue defect management, and oral surgeons, expert in stabilizing bone fractures using dental appliances.

Fig. 2.14 (A–D) Upper and lower eyelid repair with a temporal and cheek flap, respectively, according to Fricke. (Reproduced from Fritze HE, Reich OFG. *Die plastische Chirurgie*. Berlin: Hirschwald; 1845.)

Hippolyte Morestin (1868–1919), who worked with the dentist Charles Auguste Valadier (1873–1931) at Hôpital Val-de-Grâce (Paris), first realized the importance of such a team approach. For this he is considered the pioneer in facial reconstructive surgery.

In 1915, the New Zealand otolaryngologist Harold Gillies (1882–1960), at that time working in France on behalf of the Red Cross, visited Val-de-Grâce military hospital. He was much impressed by the work of Hippolyte Morestin and Valadier pushed him to take care of facial disfigurements. In 1917, upon his return to the UK, Gillies established a center for the management of face and jaw injuries at Queen's Hospital, Sidcup. It became the referral center in Europe. Treatment was provided to British and allied soldiers wounded in the Battle of the Somme (July 1, 1916), where Britain suffered almost 500 000 casualties with an enormous number of dramatic facial mutilations (Fig. 2.16). Gillies operated among a multidisciplinary team with William Fry (1889–1963) and Henry Pickerill (1879–1956) as dental surgeons, and a qualified group of anesthesiologists. He systematized new reconstructive procedures, like the tubed flap, described by the Russian Vladimir Filatov (1875–1956),⁴⁸ which allowed the coverage of large skin defects, but also skin flaps, bone, cartilage, and skin grafts (Fig. 2.17). Gillies reported his experiences in *Plastic Surgery of the Face*, issued in 1920.⁴⁹

In Germany Erich Lexer (1867–1937), one of the founders of maxillofacial surgery, built up a vast experience on the repair of the face, mandible, and eye socket using cartilage, bone, skin, and fat graft. He published a book on reconstructive surgery in 1920.⁵⁰

The Dutch surgeon Johannes Esser (1877–1946) was active at Tempelhof Hospital, Berlin, and in Vienna. Between 1916 and 1918 Esser codified some of the flaps currently used today: cheek rotation⁵¹ (Fig. 2.18), bilobed, island, and arterialized flaps, which he called biological flaps.⁵² In Italy, Gustavo Sanvenero Rosselli (1897–1974) was appointed head of the *Padiglione per i Mutilati del Viso* (Pavilion for Facial Cripples) in Milan (Fig. 2.19). It became a European referral center for reconstructive surgery and was visited by surgeons from all over the world.

Frantisek Burian (1881–1965) headed an important plastic surgery unit in Prague, Czechoslovakia.

Fig. 2.16 Dramatic facial mutilations from World War I. (Reproduced from Pickerill HP. *Facial Surgery*. Edinburgh: Livingstone; 1924.)

In the US the specialty only grew after World War I. Vilray Blair (1871–1955), trained at Sidcup, established the first independent unit in the US for the care of complex maxillofacial injuries at Walter Reed Hospital. Other renowned reconstructive surgeons were Robert Ivy, Truman Brophy, John Staige Davis, and the Armenian Varaztad Kazanjian.

The training programs

By the end of World War I, reconstructive techniques had achieved surprising results. Transfer of skin flaps (tubed or pedicled) and use of grafts (skin, cartilage, bone, fat) became routine procedures. New units were established all over the world. Thus, the need for training programs, where young doctors could become familiar with reparative methods, was essential. Queen's Hospital at Sidcup, headed by Sir Harold Gillies, was probably the most famous for the management of facial injuries. Anesthesia improved considerably thanks to Ivan Magill, who developed nasal and endotracheal intubation. Other training programs in the UK were organized by Sir Archibald McIndoe, Rainsford Mowlem, and Pomfret Kilner.

In Paris, the otorhinolaryngologist Fernand Lemaître (1880–1958) established a residency at the International Clinic of Oto-Rhino-Laryngology and Facio-Maxillary Surgery, having Eastman Sheehan (1885–1951), Professor of Plastic Surgery at Columbia University New York, as course director

(Fig. 2.20). The 2-year fellowship included an intense program of lectures and practical surgical demonstrations. Attendees from various parts of Europe and the US were numerous. Among them was the Italian Gustavo Sanvenero Rosselli, later appointed head of the Plastic Surgery Clinic in Milan. In the US the first training program was organized by Wilray Blair at Washington University in St. Louis.

The birth of the scientific societies

The aim of the scientific societies was to improve the scientific level of the specialty and to defend the public from charlatans. The first society was the American Association of Oral and Plastic Surgeons, established in 1921 by Truman Brophy (1848–1928), who strongly supported close cooperation between oral and plastic surgeons. Initially membership required the MD and DDS degrees.

In Europe, the first society was the Société Française de Chirurgie Réparatrice Plastique et Esthétique, established in 1930 by Charles Clauoué (1897–1957) from Bordeaux and Louis Dartigues (1869–1940) from Paris. It only lasted 2 years.

In 1931, Jacques Maliniak (1889–1976) founded the American Society of Plastic Surgeons.

The first supranational society was the Société Européenne de Chirurgie Structive, created in 1936 by the Belgian Maurice Coelst (1894–1963) (Fig. 2.21), with the aim of gathering annually all those international specialists interested in the new discipline.⁵³ The term *structive* was coined by Johannes Esser, as he considered it more appropriate than “plastic” to emphasize the repairing concept.

In 1937, Vilray Blair organized the American Board to certify real plastic surgeons.

The scientific journals

At the time of the foundation of the American Society (1931), the Belgian Maurice Coelst established and edited the *Revue de Chirurgie Plastique* (Fig. 2.22). The journal, the first one on this topic, played an important role in the history of plastic surgery between the two wars. Thanks to an international editorial board, which included the most prestigious plastic surgeons, the journal published high-quality papers written by Gillies, Maliniak, and Rethi, the proceedings of the American Society of Plastic Surgery and those of the Société Française de Chirurgie Réparatrice Plastique et Esthétique.⁵⁴ Papers appeared in the author’s preferred language and were summarized in English, French, and German.

In 1935, the *Revue de Chirurgie Plastique* changed its name into *Revue de Chirurgie Structive*, becoming the official journal of the Société Européenne de Chirurgie Structive. The *Revue* lasted until the end of 1938 (8 years), when it ceased publication, due to the advent of World War II.

In 1946, the *Plastic and Reconstructive Surgery Journal* was established and Warren B. Davis was appointed as an editor.

The bases for the official recognition of plastic surgery as an independent specialty were settled.

Postwar plastic surgery

Recent history sees an incredible development of new reconstructive procedures, initiated in the 1960s with the recognition of arterialized flaps, continuing with the clinical definition of the cutaneous vascular territories nourished by a single vessel, first identified by Carl Manchot (1866–1932) in 1889⁵⁵ (Fig. 2.23), and culminating with their microvascular transfer.

The application in surgical practice of musculocutaneous flaps, originally described by the Italian Iginio Tansini (1855–1943)⁵⁶ (Fig. 2.24), the introduction of craniofacial techniques, developed in the late 1960s by Paul Tessier (1917–2008),⁵⁷ the systematization of breast reconstruction, the use of fat grafting for numerous aesthetic and reconstructive indications,⁵⁸ and even the most recent face transplantation, constitute further achievements of our specialty.

Aesthetic surgery

The origin

The history of aesthetic surgery begins in 1845, when Johann F. Dieffenbach (1794–1847) described external incisions to reduce large, hanging noses with the dual purpose of modifying the nasolabial angle and decreasing the size of the nose.⁵⁹ No illustration was provided. The same operation was undertaken a few years later by the Latvian surgeon Julius von Szymanowski (1829–1868), who reported it in his “*Operatizij poverchnosti...*” (*Handbook of Operative Surgery*),⁶⁰ showing the illustration of the procedure. The change of the nasolabial angle and the aesthetic goal of the procedure were emphasized.

Correction of prominent ears, performed in 1881 by the New York surgeon Edward Ely (1850–1885) and modifications of nasal appearance are considered among the first purely cosmetic procedures.⁶¹

Fig. 2.22 The first issue of the *Revue de Chirurgie Plastique*, established by M. Coelst in 1931.

Fig. 2.23 The cutaneous vascular territories nourished by a single vessel. (Reproduced from Manchot C. *Die Hautarterien des menschlichen Körpers*. Leipzig: Vogel; 1889.)

Fig. 2.25 Jacques Joseph (1865–1934), carving a piece of ivory, before inserting it into the nasal dorsum. (Reproduced from Joseph J. *Nasenplastik und sonstige Gesichtsplastik nebst einem Anhang über Mammoplastik*. Leipzig: Kabitzsch; 1931.)

In 1887, John Orlando Roe (1848–1915), an otolaryngologist from Rochester, showed members of the New York Medical Society that reduction of a bulbous or “pug nose,” as he named it, under local anesthesia and on outpatient basis, was feasible.⁶² Four years later, he presented hump removal using scissors at the same society.⁶³ The following year, Robert Weir (1838–1927), a general surgeon from New York, described alar base excision, now eponymously named “Weir operation”, to lower an overprojected nose.⁶⁴

On the other side of the ocean, in Europe, aesthetic rhinoplasty started in Berlin, in about the same period, with Jacques Joseph (1865–1934), who codified the steps of the technique in a rigorous sequence, still used today after almost 100 years, with minimal variations (Fig. 2.25). For at least 20 years,

Fig. 2.24 The latissimus dorsi musculocutaneous flap according to Tansini. (A) Flap outlined. (B) Flap transposition. (C) Final result. (Reproduced from Tansini I. *Sopra il mio nuovo processo di amputazione della mammella*. Gazz Med It 1906;57:141.)

Joseph managed the aesthetic rhinoplasty scenario in Europe, receiving the most famous patients from every part of the world. His experience was included in a monumental work, *Nasenplastik und sonstige Gesichtsplastik (Rhinoplasty and other Facialplasties)*, published in 1931, which remained an unsurpassed text for several decades.⁶⁵

The development

The problem of the beauty doctors

The real explosion of aesthetic surgery took place in Europe and in the US between the two world wars.

The importance given to personal appearance produced, in the early 20th century and especially during the interwar period, a horde of quacks, charlatans, and beauty doctors often working in beauty salons, exclusively on a commercial basis. They advertised in newspapers, women's magazines, and yellow pages as cosmetic surgeons. They appealed to popular naivety by promising a more attractive look with simple, fast procedures on an outpatient basis, at relatively high cost and by insisting on how beautiful faces and noses were crucial in creating a favorable first impression for finding a job, or expanding social relationships.⁶⁶

To establish a barrier against beauty doctors and in an attempt to isolate them, true plastic surgeons, practicing reconstructive as well as aesthetic procedures, founded plastic surgical societies (see above). However, it was not an easy task because the general public was more interested in the achievements of cosmetic surgery than in the outcome of reconstructive procedures.

An example is given by Charles C. Miller (1880–1950), regarded as an “unscrupulous charlatan” by some or “the father of modern cosmetic surgery” by others for having published in 1907 *The Correction of Featural Imperfections*, a pioneering work on aesthetic procedures, where facial operations, such as double-chin excision, eyelid and nasolabial fold modification, were illustrated.⁶⁷ Miller made extensive use of paraffin injections, considered the ideal filler for improving saddle nose and cutaneous depressions. When paraffin was abandoned because of devastating local and systemic sequelae (paraffinomas, pulmonary embolism, phlebitis), he replaced it with crude rubber mixed with gutta-percha and ground in a mill.⁶⁸

Another borderline cosmetic surgeon was Henry J. Schireson (1881–1949), who knew a moment of fame in the US for having successfully operated on a British actress. Apart from this episode, he faced a series of lawsuits for malpractice which culminated in having his license revoked for a period of time. In 1944, *Time* defined him as the “king of quacks”.

Trained surgeons made considerable efforts to establish a positive view of plastic surgery. Their talent contributed to the transformation of a field regarded with suspicion into an accepted branch of surgery. Eastman Sheehan (1885–1951), Jacques Maliniak (1889–1976), Jerome P. Webster (1888–1974), Vilray Blair (1871–1955), Ferris Smith (1884–1957), and others all played important roles in creating plastic surgery's professional and public image during the years the specialty was taking shape. Sheehan, course director at Lemaître's International Clinic in Paris (Fig. 2.20), was elected President of the American Association of Plastic Surgeons in 1935, despite the controversial view of him by many American colleagues, who

Fig. 2.26 Result of a facelift carried out by Suzanne Noël (1878–1954) about 1925. (Reproduced from Noël S. *La Chirurgie Esthétique. Son rôle Sociale*. Paris: Masson, 1926.)

regarded Sheehan as a publicity-seeking skilled operator. Maliniak is best remembered as the founding member of the American Society of Plastic Surgeons in 1931. He was a prolific writer; *Sculpture in the Living* (1934)⁶⁹ and *Rhinoplasty and Restoration of Facial Contour* (1947)⁷⁰ are some examples. He had an important aesthetic surgical practice in New York, mainly for nose and breast. Webster was one of the founding fathers of US plastic surgery and a talented surgeon in the reconstructive as well as aesthetic fields. Smith, like Sheehan, was course director at Lemaître's International Clinic in Paris, and author of *Reconstructive Surgery of the Head and Neck*, issued in 1928 with a section devoted to aesthetic rhinoplasty.⁷¹

In Paris, Suzanne Noël (1878–1954), active feminist and founder of the Soroptimist Club of Europe, established a successful solo practice in the very exclusive 16th *arrondissement*. Her operations were simple but effective, mainly related to facial rejuvenation and entirely performed on an outpatient basis (Fig. 2.26). Major surgery, such as abdominoplasty or mammoplasty, was executed in a private clinic. In 1926, she published *La Chirurgie Esthétique. Son Rôle Sociale*, one of the first textbooks on this topic and the first written by a woman.⁷² In 1928 she was awarded the Legion of Honour. Raymond Passot (1886–1933), a leading Parisian aesthetic surgeon, added innovative techniques for breast ptosis, abdomen and facial rejuvenation. His book *La Chirurgie Esthétique Pure*, dating from 1931, showed a wide range of operations in the field of aesthetic surgery⁷³ (Fig. 2.27). Julien Bourguet (1876–1952), another Parisian cosmetic surgeon, became renowned for having first presented the transconjunctival approach for baggy eyelid correction in 1929.⁷⁴

Fig. 2.27 The cover of the book on aesthetic surgery by Raymond Passot (1886–1933), published in 1931.

In Berlin, Jacques Joseph carried out a wide variety of cosmetic operations from rhinoplasty to reduction of prominent ears, facelifting and reduction mammoplasty.⁶⁵ Eugen Holländer (1867–1932) is credited with being the first one who reported on a facelifting. “Victim myself of the art of feminine persuasion, a few years ago, I performed the excision of a piece of skin along the hairline and the natural folds of the ageing wrinkles and I rejuvenated the drooping cheek for the satisfaction of the beholder”.⁷⁵ In a later publication he affirmed that this occurred in 1901 and that the patient was a Polish aristocrat.

In the same paper, Holländer showed two cases of facial atrophy treated by him with fat injection, and this was the first account reported in the literature.

Postwar aesthetic surgery

After World War II and in more recent years, aesthetic surgery grew significantly. The number of plastic surgeons around the world increased and the specialty expanded. Techniques for the correction of noses, faces, necks, eyelids, ears, chins, breasts, and abdomens improved considerably. New operations for solving a myriad of cosmetic problems developed. A typical example is management of the hypoplastic breast. Over the years it was treated with paraffin, sponge implants, fat grafts, and liquid silicone, with poor or unpleasant results. In the mid-1960s the silicone mammary prosthesis appeared on the market, representing the first convincing solution. Liposuction, introduced in the mid-1980s, soon became one of the most popular procedures. Faceliftings, fillers, botulinum toxin, and fat injection favorably improved the demand for facial rejuvenation.

Psychological aspects of cosmetic surgical and minimally invasive treatments

David B. Sarwer and Mark B. Constantian

Disclosures: Dr. Sarwer has consulting relationships with Kythera, Medtronic, and Neothetics.

SYNOPSIS

- The last two decades have witnessed a dramatic increase in the number of persons who undergo cosmetic surgery and minimally invasive medical treatments designed to improve their appearance.
- Plastic surgeons have long been interested in the psychological factors that motivate individuals to undergo these procedures as well as the psychological changes that they frequently observe postoperatively.
- Early reports in this literature characterized most persons interested in changing their appearance with cosmetic surgery as suffering from a range of psychopathological conditions.
- More recent investigations of patients have focused on psychopathology but also other motivations.
- Body image dissatisfaction is commonly believed to be one of the strongest motivations for surgery. For some patients, however, this dissatisfaction may be severe and suggestive of the presence of body dysmorphic disorder or other forms of psychopathology with a body image component. Thus, these conditions are likely of greatest relevance to plastic surgeons.

The popularity of cosmetic surgical and minimally invasive treatments

According to the American Society of Plastic Surgeons, 15.6 million cosmetic surgical and minimally invasive treatments were performed in 2014.¹ The vast majority, nearly 14 million, were minimally invasive procedures such as Botox® injections and soft tissue fillers. Over 1.6 million were the traditional cosmetic surgical procedures such as breast augmentation and rhinoplasty. The total number of procedures has increased by 111% since 2000.¹ While these numbers certainly reflect the popularity of cosmetic procedures, they likely underestimate the true number of procedures performed annually in the United States, as physicians from specialties other than plastic surgery now offer many of these treatments.

There are a number of potential explanations for the growth in popularity in cosmetic surgery and minimally invasive treatments.^{2,3} Many treatments are safer and have shorter recovery periods than before. The shorter recovery period, as well as the much lower cost of minimally invasive treatments, have facilitated their rapid growth over the decade. Cosmetic procedures readily lend themselves to direct-to-consumer advertisements. In most major metropolitan areas, advertisements for these procedures are frequently seen on billboards and in local magazines. This marketing likely has contributed to the growth. The larger mass media and entertainment industries likely have contributed as well. Cosmetic surgery has long been a very popular topic for women's (and men's) fashion and beauty magazines, where articles often describe the latest advances in the field. The past decade also witnessed unprecedented coverage of cosmetic surgery on television, both in traditional media coverage and as the focus of reality-based television programs.⁵ At the same time, a growing number of celebrities publicly revealed their experiences with cosmetic surgery, a phenomenon not seen in Hollywood decades ago. These more overt influences play against a backdrop of relentless images of physical perfection depicted in magazines, television programs, movies, and the internet. The end result is that consumers can't help but be exposed to depictions of beauty as well as the message that cosmetic medical treatments are part of the path to physical perfection.

There are other potential explanations for the growth of cosmetic surgery as well. Evolutionary theories of physical attractiveness – which suggest that physical characteristics that demonstrate reproductive potential are the ones that are often seen as being most physically attractive – may play a role. Many facial procedures are undertaken to help an individual look more youthful and/or enhance their facial symmetry, key markers of physical attractiveness. Liposuction and abdominoplasty can decrease an individual's waist-to-hip ratio, which is another demonstrated marker of reproductive potential and “signal” of physical attractiveness.

Social psychological research on the role of physical appearance in daily life also can be used to understand the growth of cosmetic surgery as well as other appearance-enhancing behaviors. This research repeatedly has found that individuals who are more physically attractive are judged to have a number of more positive personality traits and receive preferential treatment in a range of social situations across the lifespan.⁶ With this in mind, interest in cosmetic surgery and minimally invasive treatments share similarities with other self-enhancement strategies, such as eating a healthy diet and exercising regularly.⁷

Psychosocial characteristics of patients interested in cosmetic surgery and minimally invasive treatments

Over the last 60 years, a large body of research on the psychological aspects of cosmetic surgery and minimally invasive treatments has developed.⁸ Many studies have investigated the psychological characteristics of patients who pursue these procedures; others have looked at the relationship of these characteristics to treatment outcomes. The first studies of this issue, conducted by plastic surgeons in collaboration with psychiatrists (many of whom appeared to be working from a psychodynamic theoretical orientation) involved clinical interviews of patients prior to their procedures. Perhaps not surprisingly, these studies described large numbers of patients as suffering from significant psychopathology.^{9,10} Large numbers of individuals were characterized as suffering from depression, personality disorders (typically narcissistic personality disorder) and even schizophrenia. Many of these early reports also contain elaborate interpretations of the role of unconscious conflicts and poor parental relationships in the decision to seek surgery. There is no evidence, however, to suggest that such interpretations are necessarily valid or useful in determining patients' appropriateness for surgery.^{11,12} As could be anticipated, those patients suffering with these issues were thought to be likely to experience poor postoperative psychological outcomes.

Studies conducted since the 1980s typically have included the use of psychometric measures of personality characteristics rather than or in addition to clinical interviews of prospective patients. These studies, as compared to the previous investigations, typically have found less psychopathology.¹³⁻¹⁶ Nevertheless, both sets of studies suffer from methodological problems that have made interpretation of these conflicting findings difficult.^{11,12,17} Thus, the rate of psychopathology among cosmetic surgery patients remains poorly understood. Perhaps more importantly, the relationship between preoperative psychopathology and postoperative outcomes, with few exceptions, is largely unknown.

Much of the more contemporary research on the psychosocial characteristics of cosmetic surgery patients has focused on two issues. The first is the motivations of persons who present for these procedures; body image dissatisfaction is believed to be central to these motivations. The second is the occurrence of formal psychopathology and whether the presence of significant psychiatric illness contraindicates treatment.

Body image dissatisfaction as a motivation for cosmetic medical treatment

Patients present for cosmetic medical treatments with a variety of motivations. These motivations have been described as internal (e.g., desire to improve one's self-esteem) or external (e.g., undergoing surgery in order to find a romantic partner).¹⁸ Although patients may struggle to verbalize their specific motivations for surgery to others (including friends, family members, and their treating physician), those with internal motivations are thought to be more likely to have their postoperative expectations met.¹⁹

Body image dissatisfaction is believed to be the most common motivation for a cosmetic procedure. The last several decades have witnessed a growing interest in the psychological construct of body image.²⁰ Body image has been defined in several ways. A commonly used definition suggests that body image consists of perceptions, thoughts, and feelings associated with the body and bodily experience. While this definition describes the multidimensional nature of the construct, it does not highlight body image behaviors, such as motivations for changing one's appearance through cosmetic procedures. Cash and Smolak have described body image as "the psychological experience of embodiment".²¹ This description conveys a sense of importance of the role of body image in larger psychological constructs like quality of life.

Body image is believed to contribute to self-esteem and quality of life.^{22,23} Much of the early research on body image focused on the weight and shape concerns of individuals with eating disorders. As research into the global obesity problem matured in the 1990s, the body image concerns of overweight and obese individuals garnered more attention.²⁴ Body image concerns can be thought of as both global and specific. Body image dissatisfaction is often correlated with body weight.²² However, the strength of this relationship is not as strong as would be intuitively thought. This finding is consistent with theories of body image, which have suggested that there may be little relationship between what one thinks about the body and the objective reality of one's appearance.²¹

Independent of body weight, most individuals also report more concerns with specific features of their appearance. This is particularly true among individuals who presented for cosmetic procedures, who often report dissatisfaction focused on a given feature rather than a more global dissatisfaction with their entire body. Women are typically far more dissatisfied with their body image than men.²³ Differences also exist across ethnic groups. African-American women, as compared to Caucasian women, typically report less body image dissatisfaction. Among ethnic groups, body image dissatisfaction appears to be related to the degree of acculturation into more Westernized lifestyles.

Some degree of body image dissatisfaction appears to be "normative" in Western society and likely results from society's pervasive emphasis on thinness as the ideal body type. Body image dissatisfaction is believed to motivate a number of appearance-enhancing behaviors, including weight loss, physical activity, fashion and cosmetic purchases, and cosmetic procedures.²⁴ Body image dissatisfaction, and its role in the pursuit of cosmetic medical treatments, has been the focus

of much of the recent study of cosmetic surgery patients.²⁵⁻²⁷ Individuals who seek cosmetic procedures typically report heightened body image dissatisfaction preoperatively.^{7,28-31} For example, breast augmentation candidates report greater dissatisfaction with their breasts compared to other small-breasted women who do not seek breast augmentation.^{13,15} Similarly, individuals interested in rhinoplasty reported more appearance concerns as compared to those of age- and gender-matched controls presenting for non-appearance-altering surgery.³² Thus, some degree of body image dissatisfaction is believed to be a prerequisite to cosmetic surgery. At the same time, body image dissatisfaction, particularly extreme body image dissatisfaction that impacts daily functioning, is a symptom of a number of psychiatric disorders. These include eating disorders, social anxiety disorder, and gender dysphoria. While all psychiatric disorders are likely to be represented among the large population of persons presenting for cosmetic treatments, the psychiatric disorder with perhaps the greatest relevance to cosmetic medical treatment is body dysmorphic disorder. At the same time, eating disorders and depression also warrant particular attention.

Formal psychopathology among patients interested in cosmetic surgical and minimally invasive treatments

Body dysmorphic disorder

Body dysmorphic disorder (BDD) is characterized as a preoccupation with a slight or nonobservable defect in appearance that is associated with obsessive thinking and compulsive behaviors and which leads to a disruption in the activities of daily life.³³ Case reports of patients who likely had the disorder, described as “minimal deformity” or “insatiable” patients, appeared in the plastic surgery and dermatology literatures in the 1960s and 1970s.³⁴⁻³⁷ These case reports, appearing nearly two decades before BDD was formally recognized as a psychiatric disorder, detailed patients who requested multiple procedures to improve slight or imagined defects in appearance; most reported significant dissatisfaction with postoperative treatment as well.

Identifying and diagnosing BDD in cosmetic treatment settings can be challenging.^{38,39} According to DSM-5’s first diagnostic criterion for BDD, an individual must be preoccupied with one or more perceived defects in appearance which are either “slight” or nonobservable to others.³³ Most patients presenting for cosmetic treatments have “normal” features that that they wish to enhance; others may desire correction of slight imperfections. Thus, the majority of patients could meet this criterion.

The second diagnostic criterion describes engagement in repetitive, appearance-focused behaviors, such as comparing one’s appearance to that of other people or repeatedly checking one’s appearance in the mirror. Many cosmetic medical patients engage in these behaviors; others report that they have spent large amounts of time reviewing images of celebrities in order to find examples of how they wish specific features to look. It is not uncommon for individuals who seek cosmetic treatments to report self-consciousness in social situations or

in situations where their perceived “defect” may be more noticeable to others (e.g., a woman with concerns about her nose size may report self-consciousness when someone sits next to her at a restaurant). Still, others may avoid such situations or engage in camouflaging behaviors. These examples of concerns and behaviors, while indicative of body image dissatisfaction, likely do not meet the third criteria for BDD (experiencing clinically significant distress or impairment in social, occupational, or other important areas of functioning). However, a patient who is reporting symptoms of anxiety and depression because of her nose, or who is socially isolated or unable to work because of her appearance concerns, likely would meet diagnostic criteria. Thus, in cosmetic settings, the degree of distress and impairment in functioning experienced by the patient likely differentiates a cosmetic surgery patient with “normative” body image dissatisfaction from one who is in fact suffering from BDD.^{38,39}

Rates of BDD among cosmetic treatment populations

A number of studies have investigated the rate of BDD among individuals presenting for cosmetic surgery.⁴⁰ Among American samples, rates of 7–13% have been reported.^{7,41,42} International studies have reported rates ranging from 2.9%–53%.⁴³⁻⁵¹ Studies with the highest rates of BDD have typically used unspecified clinical interviews to establish the diagnoses. Thus, there are concerns about the validity of these results. International studies which have used more rigorous methods have found rates ranging from 3.2 to 16%.

Seven studies have investigated the rate of BDD among patients seeking rhinoplasty and reported rates ranging from 12–33%.⁵²⁻⁵⁶ The higher rates reported among rhinoplasty patients is not surprising given that the nose is one of the most common areas of concern among persons with BDD.⁵⁷ Among 13 patients seeking Botox® injections for perceived hyperhidrosis, 23% met criteria for BDD.⁵⁸ In a study of 137 patients in Australia, 2.9% met criteria for BDD.⁴³ Investigators have also turned their attention to evaluating BDD among patients seeking less common procedures, including requests for genital cosmetic surgery. Veale and colleagues found that 18% of women seeking labiaplasty met criteria for the diagnosis.^{59,60}

BDD is similarly common among persons who seek dermatological treatment, with rates typically ranging from 4.2–15%.^{50,61-68} Acne patients treated with isotretinoin (Accutane) have been found to be twice as likely to meet criteria for BDD,⁶⁶ a finding that is of interest given the association between suicidality and use of this treatment as well as the high rates of suicidal ideation and attempts reported among those with BDD.⁶⁹

BDD also has been studied among persons seeking reconstructive procedures. Three studies have examined the rate of BDD among persons seeking reconstructive surgical procedures, such as scar revision and breast reconstruction, with 2–16% of patients reporting distress or concern with their appearance consistent with BDD.^{41,42,70} A recent study examined BDD symptoms among 188 women undergoing breast reconstruction secondary to mastectomy; 17% met criteria for BDD, and women undergoing delayed reconstruction (versus immediate) were more likely to meet criteria.⁷¹ Although women with actual breast deformities due to mastectomy

would likely not meet full criteria for BDD, individuals with objective defects can become preoccupied with their appearance and experience significant distress and functional impairment.

Use of cosmetic medical treatments among individuals with BDD

A number of studies have investigated the history of cosmetic procedures among persons with an established diagnosis of BDD.⁷²⁻⁷⁴ In one of the earliest studies, 48% of individuals with BDD reported having sought cosmetic or dermatological treatment, with 26% having undergone one or more cosmetic procedures.⁷⁴ Two larger studies have suggested that over 70% of patients had sought and more than 64% had received a cosmetic treatment.^{72,73} These reports are not particularly surprising. Individuals with BDD believe, often with delusional intensity, that their appearance is truly flawed. Many believe that the only way to reduce their appearance-related distress is to actually change their appearance via cosmetic medical treatment. In fact, individuals with BDD are nearly as likely to pursue treatments from dermatologists, paraprofessionals, and plastic surgeons as they are from psychologists or psychiatrists.⁷⁵

While many individuals with BDD are able to obtain cosmetic treatments, a sizable percentage report that they were unable to receive a desired treatment. Surveys suggest that 80% of plastic surgeons and 62% of dermatologic surgeons have refused to perform cosmetic procedures on individuals believed to have BDD.^{76,77} Unfortunately, in today's competitive cosmetic procedure market, patients with BDD who are denied treatments by one provider can engage in "doctor shopping" until they find a provider willing to perform their desired procedure.

In some instances, patients with BDD can become so distressed about their perceived appearance defects that they take matters into their own hands and perform "do-it-yourself" procedures.^{78,79}

Cosmetic treatment outcomes among persons with BDD

Individuals with BDD are often convinced that cosmetic treatments will alleviate their appearance-related preoccupation and distress. However, evidence suggests that cosmetic treatments rarely improve BDD and patients are frequently dissatisfied with treatment outcomes.^{72,74,78,79} For example, a study of 200 persons with BDD found that only 3.6% of 528 procedures resulted in improvement in overall BDD symptoms.⁷²

Few studies have prospectively examined cosmetic treatment outcome among individuals with BDD. Tignol and colleagues⁸⁰ evaluated 24 cosmetic surgery patients who sought treatment for minimal appearance defects; 10 of these patients had been diagnosed with BDD preoperatively. Five years later, seven of the ten patients had undergone cosmetic surgery. Among these seven, remission was reported by only one, while the other six continued to meet diagnostic criteria for BDD. New areas of concern developed in five patients. A prospective study of 166 individuals who sought rhinoplasty found that greater preoperative BDD symptoms predicted dissatisfaction with treatment postoperatively.⁸¹ Similarly, a

study of 127 women who had undergone cosmetic treatment reported that women with higher levels of BDD symptoms were more likely to be dissatisfied with their treatment outcome and were more likely to have ever been rejected for cosmetic treatments compared to those with low BDD symptom levels.⁸² Phillips *et al.* conducted a prospective, naturalistic study of 161 individuals diagnosed with BDD and found that receipt of cosmetic treatment did not predict remission from BDD one year later.⁸³ Overall, these findings are consistent with retrospective reports regarding the likelihood of poor outcomes following cosmetic treatments among persons with BDD.

In contrast, two recent studies have suggested that some individuals with BDD may benefit from cosmetic treatments. A prospective study of 31 patients with mild to moderate BDD who sought and received rhinoplasty found that, postoperatively, 81% had a complete remission of BDD symptoms; 90% were satisfied with their postoperative outcome.⁸⁴ However, this study had some significant limitations, such as the small sample and inclusion of patients who were rated as having "marked nasal deformity" (calling into question whether they would meet diagnostic criteria for BDD). Thus, the conclusion that rhinoplasty benefits patients with mild to moderate BDD is likely unfounded.⁸⁵ Another recent prospective study of women seeking labiaplasty ($n = 49$), nine of whom met criteria for BDD via self-report and clinical interview preoperatively, found that eight experienced a remission from BDD symptoms at a 3-month postoperative assessment,⁶⁰ and four reported longer-term remission from BDD. Interestingly, the one woman who still met criteria for BDD postoperatively did so because of a different appearance preoccupation (nose) but reported satisfaction with her labiaplasty.

In addition to the risks for poor outcomes and dissatisfaction with treatment, patients with BDD are known to have high risks for suicide. The mean annual suicide attempt rate for persons with BDD is 2.6%, while the mean suicidal ideation rate is 57.8%.⁶⁹ Unmet cosmetic treatment expectations could fuel suicidal ideation and/or suicide attempts in some patients with BDD. Treating physicians also face risks when knowingly or unknowingly performing cosmetic procedures on patients with BDD. At a minimum, patients with BDD may present as being "difficult" or hard to manage for providers and their staff.^{86,87} Providers may also face legal risks, as patients with BDD have threatened or pursued legal action against their treating physicians.^{42,76,77} Surveys of cosmetic treatment providers suggest that between 9% and 29% of physicians have been threatened legally by a patient with BDD.^{76,77} Two percent of cosmetic and dermatological surgeons report being threatened with physical harm by patients with BDD. Tragically, some providers have been murdered by patients with or suspected of having BDD.⁸⁸

Due to the safety risks for both patients and providers along with the evidence that cosmetic treatment outcomes among persons with BDD are typically poor, BDD appears to be a contraindication for cosmetic treatments. Given that persons with BDD frequently seek cosmetic treatments, screening for BDD is recommended in cosmetic treatment settings.

Clinical presentation of patients with BDD

A number of still-unanswered questions emerge from the body image and body dysmorphic disorder literature: (1)

What drives patients with normal features or minimal deformities to undergo repeated plastic surgeries on one or more body areas? (2) Why is there often such poor correlation between the degree of preoperative deformity and the drive to surgery that it provokes? (3) Why are patients who have undergone multiple cosmetic surgeries so likely to be unhappy with their surgical results, even when they appear to be successful? (4) If body dysmorphic disorder is driven by the media and the obsession of popular culture with beauty and being thin, why are some reconstructive patients just as difficult to please?⁸⁸ (5) Why do some postoperative patients become so irrationally angry that they are beyond reason? (6) Finally, why do many of these unhappy patients have turbulent family relationships?

Twenty years ago, one of us (MBC) saw three patients in relatively quick succession who all had tumultuous postoperative courses after reconstructive nasal surgery – doubly ironic because each patient had an entirely successful surgical outcome. One was a university professor who resigned her position to become a recluse because she believed that her reconstructed nose now pointed toward the ceiling. She remained inconsolable by logic or photographic analysis. When I advised against further surgery, she wrote a letter that concluded, “I feel so terribly betrayed... You have robbed me of my family, my friends, and my joy in living.” The second patient was a physician’s wife who hid in her bedroom for months after surgery, unable to function or care for her family because of perceived but invisible nasal deformities. The third patient abandoned his business, abused alcohol heavily, and unsuccessfully tried to amputate his reconstructed nose.⁷⁸ All of these patients seemed like excellent surgical candidates preoperatively but revealed themselves to meet the diagnostic criteria for BDD after surgery. Postoperatively, they could not be reassured: all were convinced that their results were failures and that they needed additional surgery.

Soon thereafter, a young man came for secondary rhinoplasty who said, “I had body dysmorphic disorder but I have recovered.” With the approval of his therapist, one of us (MBC) performed his revision rhinoplasty. His postoperative course was smooth. Later, the surgeon requested a letter describing his body dysmorphic disorder experience, since most surgeons had never treated patients who recovered. His four-page, single-spaced autobiography chronicled an intense, traumatic childhood, the desertion of his father, an abusive stepfather who relentlessly ridiculed the child’s nose, family alienation, his brother’s suicide, drug abuse, and his mother’s abandonment. This observation led to further speculation on the relationship between BDD and childhood abuse or neglect, which was subsequently reported in the literature.⁸⁹

This hypothesis led to a report of 20 secondary rhinoplasty patients with similar personal and family characteristics who had undergone a total of 134 rhinoplasties, almost 7 each.⁹⁰ All had undergone multiple rhinoplasties and other cosmetic operations; they were perfectionistic, demanding, and depressed; and 80% of their original unoperated noses had been straight and symmetrical. When asked, “Why did you have surgery?” they gave answers like these: “Because my nose wasn’t perfect enough”; “Because my mother wanted me to be as beautiful as she was”; “Because my mother told me, ‘You were the ugliest baby I ever saw’”; and perhaps the saddest one, “I had surgery so people would love me.”

These observations led to further study of the psychosocial history of 100 secondary rhinoplasty patients.^{91,92} Half of the patients originally had noses with dorsal humps (the most common motivation for rhinoplasty), and half originally had straight noses. Twenty-nine had straight, functional noses that the patients knew were normal; yet they had surgery anyway. The data suggested that the smaller the deformity, the greater the likelihood of depression, history of childhood trauma, and the lower the patients’ satisfaction with the surgical results. Secondary rhinoplasty patients who originally had straight noses had undergone three times as many rhinoplasties and had three times the trauma prevalence of patients who originally had dorsal humps. Among 29 patients who were depressed, had undergone more than three cosmetic operations of any type, and whose motivation for the first rhinoplasty had been to “perfect” a subjectively normal nose (which defines body dysmorphic disorder), the prevalence of childhood trauma was an astonishing 93%. The surgical satisfaction rate after one operation was only 3%. Subsequent studies have indicated that many revision rhinoplasty patients also screen positive for post-traumatic stress disorder, especially if they had childhood trauma histories, and that successful reconstructive surgery can decrease their avoidance and re-experiencing symptoms.⁹³ Mediation analysis indicated that a history of childhood abuse or neglect was the most significant factor connecting patient satisfaction and the number of previous surgeries; in other words, childhood trauma patients had undergone the most cosmetic surgeries and were the most likely to be unhappy with the results of additional procedures.⁹¹ Random forest analysis indicated that the number of prior surgeries was the most significant predictor of surgical success for patients who originally had dorsal humps, but that childhood trauma was the most significant factor predicting success for patients who originally had straight, normal noses.⁹²

Childhood trauma is implicated in many types of diseases, including chronic pain syndromes, fibromyalgia, cardiovascular and pulmonary disease, cancer, asthma, morbid obesity, mental health disorders, and autoimmune disease, which accounts in part for the reported incidence of body dysmorphic disorder even in reconstructive patients.^{70,71,88,94,95–99} Of particular interest and relevance to plastic surgeons is the connection between childhood trauma, eating disorders, and body image. A number of studies have shown a strong correlation between body image and childhood trauma, particularly sexual abuse, depression, eating disorders, and obesity.^{97,99–101}

What evidence is there that BDD patients display signs of neglect or abuse? One study indicated that 78.7% of 75 patients with confirmed BDD had histories of neglect or abuse.⁸⁹ Other reports document associated traits: poor social functioning, social anxiety, depression, anxiety, anger, and somatic symptoms, neuroticism, eating disorders, post-traumatic stress disorder, and obsessive compulsive disorder.^{102–112}

To date, efforts to identify abnormalities in neuroanatomy, neurotransmitters, or genetic expression or allelic variation have not yielded consistent information about the pathogenesis of body dysmorphic disorder. However, fMRIs of body dysmorphic patients have documented overactivity in the thalamus and amygdala and a left-to-right volume asymmetry in the caudate nucleus, changes that are coincidentally consistent with findings in patients with histories of childhood

trauma and post-traumatic stress disorder.¹⁰⁸ Adding even further complexity is recognition that family environment influences genetic factors, which in turn work together to create both personality and psychopathology. Although only a small number of genes have been studied to date, both genome-wide association studies and epigenetic research have documented variations in the hypophyseal–pituitary axis and dopamine and serotonin transmission that may affect susceptibility to trauma or, conversely, produce resilience.¹⁰⁹

What are the clinical implications of these relationships? Most plastic surgeons do not routinely take trauma histories or inquire about their patients' childhoods, and not every person subjected to abuse or neglect is susceptible to their damaging effects. Yet all patients have life histories. Abuse by caregivers may be disempowering or falsely empowering, distorting or destroying the traits that functional adults must possess: self-esteem, "boundaries" (self-protection and containment against offending others), a sense of reality, and the ability to live moderately and independently. Abused and neglected patients live at the extremes, depending on the types of trauma they have experienced. For example, disempowered patients lack self-esteem, cannot articulate surgical goals, forget appointments, and may manifest victim behavior; falsely empowered patients become grandiose, demand extra attention, may dictate the operative plan, and expect perfection (Table 3.1). Only when surgeons consider their patients' pasts will their current behaviors become understandable as remnants of adapted responses to abuse or neglect.¹¹⁰

The shadow factor of childhood abuse and neglect, so regrettably common in our culture, may, in part, explain why the severity of our patients' deformities does not always correspond to the drive for surgery that it provokes, why so many of their lives and family relationships are chaotic, and why it is so hard to reason with some unhappy patients. The trauma link complements what is currently known about body dysmorphic disorder and may be one of the keys to understanding some of our unhappiest plastic surgery patients.

Depression

The potential presence of major depression or other mood disorders also warrants particular attention by the physician offering cosmetic treatments. At least one study has suggested that approximately 20% of persons presenting for cosmetic surgery are engaged in mental health treatment, most typically the use of an antidepressant or other psychiatric medication.¹¹¹ Women considering breast augmentation or those with breast implants have been found to report a higher rate of outpatient psychotherapy,¹⁵ psychopharmacologic treatments,¹¹¹ and psychiatric hospitalizations,¹¹² as compared to other cosmetic surgery patients or women from the general population. Although these studies suggest that the rate of psychopathology may be higher among patients with breast implants, the investigations provided no information on the specific psychiatric diagnoses of these women.

Table 3.1 Characteristic behaviors of disempowered and falsely empowered patients

Disempowered patients	Falsely empowered patients
No self-esteem Unjustifiably untrusting or fearful Unable to make decisions Unsure of themselves or surgeon Require extra time of surgeon and staff Manifest victim behavior	Grandiosity False sense of superiority Try to dictate operative plan Expect to be seen on holidays or weekends Demand extra time of surgeon and staff Request special fees and/or discounts
Overly sensitive to surgical advice Take everything as criticism No sense of humor May exercise covert manipulations	Argue Interrupt May act offensively or manipulatively and try to control the surgical process
Unable to articulate surgical goals Seem inarticulate, disconnected, non-relational Have exaggerated or imperceptible deformities May have controlling parents or spouse	Unrealistically precise about surgical goals Expect perfection Have exaggerated or imperceptible deformities Argumentative with staff
Possible histories of alcohol abuse and/or antidepressant use Depression, migraines, fibromyalgia Eating disorders or obsessive compulsive behavior History of multiple surgeries without adequately considering risks	Possible histories of stimulant use, risk-taking, gambling, high-risk sports or professions Work or sex addictions High-intensity lives History of multiple surgeries without adequately considering risks
Unable to perform simple postsurgical care Forget appointments, unable to make decisions Do not remember or follow written instructions Request and need constant advice and reassurance via phone or email May self-injure, become reclusive or threaten suicide	Disregard perioperative instructions Demand extra, holiday, or weekend appointments Arbitrarily alter perioperative instructions Act entitled Guarded; remote; may reject routine postoperative care May become aggressive or threatening
May have body shame	May have body shame

Over the past 15 years, seven epidemiological studies investigating the relationship between silicone gel-filled breast implants and all-cause mortality have found an association between breast augmentation and suicide.¹¹³ These studies, which focused on women who received these implants for cosmetic purposes, suggest that the rate of suicide is two to three times higher than rates in other cosmetic surgery patients or estimated rates in the general population. (Women who received breast implants as part of breast reconstruction were not studied.) Potential explanations of the relationship between breast implants and suicide primarily have focused on the preoperative psychosocial status and functioning of the women.^{25,113,114} Women who undergo cosmetic breast augmentation have been shown to have a number of distinguishing demographic characteristics. They are more likely to report more lifetime sexual partners and a greater use of oral contraceptives, be younger at the time of their first pregnancy, and have a history of terminated pregnancies.^{115,116} They also have been found to be more frequent users of alcohol and tobacco.^{14,116,117} Many of these characteristics are markers of psychopathology, in and of themselves, risk factors for suicide.

Only one of the seven epidemiological studies provided any information on the psychiatric history of the women studied. This study found a higher rate of previous psychiatric hospitalizations among women with breast implants in comparison to both women who received other cosmetic procedures and women who underwent breast reduction.¹¹² A history of psychiatric hospitalizations is one of the strongest predictors of suicide among women in the general population.¹¹⁸ Unfortunately, Jacobsen and colleagues did not report information on diagnosis, history of illness, or other psychiatric treatments for the women in their sample.¹¹² Thus, more specific information on the relationship is not available. Though these studies have documented that there is a relationship between breast augmentation and suicide, it is important to note that breast implants or breast augmentation surgery does not cause suicide. Rather, it appears that the individual personality characteristics and experiences more likely contribute to the relationship.

Eating disorders

Given the excessive body image dissatisfaction reported by patients with eating disorder, these disorders may occur with some frequency among those who seek cosmetic surgery. Persons with eating disorders may erroneously believe that cosmetic treatments will improve their immense dissatisfaction with their bodies. Eating disorders may be a particular concern for women (and men) who seek body contouring procedures, including liposuction, abdominoplasty, as well as breast augmentation. These patients may mistakenly believe that these procedures can reshape their bodies in a way that restrictive eating and/or maladaptive compensatory behaviors cannot. Women who present for cosmetic breast augmentation are frequently below average weight^{13,15,31} and report greater exercise compared to physically similar women not seeking breast augmentation,¹³ both of which also may be suggestive of eating psychopathology.

In summary, the psychological functioning of cosmetic surgery patients has been of interest to both the physicians who offer these treatments, as well as mental health professionals, for decades. This interest predates the prolific growth

of aesthetic medical treatments seen in the past two decades. With the wide range of patients who seek cosmetic surgery, all psychiatric diagnoses are likely to be found. Most salient to cosmetic surgery are likely psychiatric conditions with a body image component – body dysmorphic disorder and eating disorders as well as depression. Studies suggest that between 5% and 15% of patients seeking cosmetic surgery suffer from BDD, indicating that providers may encounter these patients in their practice on a regular basis. Although it makes intuitive sense that the weight and shape concerns seen in eating disorders may be related to interest and pursuit of cosmetic surgery, research investigating this relationship is lacking. The most concerning relationship between cosmetic surgery and psychopathology is the link between breast implants and suicide. This relationship clearly warrants further study.

Psychosocial status following cosmetic medical treatments

Numerous studies have suggested that 80–90% of patients report satisfaction with the results of their cosmetic medical treatments.^{16,119–122} Patients also have been found to report significant improvements in body image.^{16,121,123–125} Most studies have found these changes within the first two years of surgery, although one investigation has shown improvements in body image enduring for five years after surgery.^{126,127}

Studies of psychosocial functioning beyond body image have produced mixed results. For example, a number of relatively recent studies have looked at changes in self-esteem following cosmetic medical treatments. This is a particularly relevant construct, as these treatments are often marketed with the promise of improving self-esteem. Some studies have documented the improvements in self-esteem.^{127–129} Other studies have not found statistically significant improvements in self-esteem.^{130–133} However, this also may be a function of methodology. For example, if asked directly whether or not surgery improved self-esteem, women who underwent breast augmentation report improvements.^{129,130,133} In contrast, studies which have used psychometric measures of self-esteem have found equivocal results.^{119,121,134–136} At least one investigation has shown that while self-esteem may improve in the first few years after surgery,¹²⁸ these benefits appear to dissipate over time.

Studies that have investigated the relationship between cosmetic medical procedures and depression also have found mixed results. Some reports show an improvement in depressive symptoms.^{137–139} In contrast, other studies have found no appreciable changes in depressive symptoms after treatment.^{126,132,140}

Postoperative satisfaction and the psychological benefits associated with cosmetic surgery may be negatively impacted by the occurrence of a postoperative complication.¹⁹ At least one study found that breast augmentation patients who experienced postoperative complications reported less favorable changes in body image in the first two years following surgery.¹²⁴ Statistics from the American Society of Plastic Surgeons indicate that approximately 50% of patients return for a second procedure at some point in the future.¹ Unfortunately, it is unclear if these patients are returning for a second procedure because they are dissatisfied with the outcome of

the first procedure or if they were satisfied with the outcome and are now interested in modifying another aspect of their appearance.

Assessment of psychosocial functioning prior to cosmetic medical treatment

Physicians who perform cosmetic surgical and minimally invasive treatments should evaluate and monitor the psychosocial status and functioning of patients who seek these procedures. Most patients who present for these treatments are thought to be psychologically stable. Prospective patients typically have specific appearance concerns, internal motivations, and realistic postoperative expectations. Thus, most patients do not need a psychological evaluation prior to treatment. Nonetheless, a sizable minority of individuals who present for aesthetic medical procedures may present with a range of psychiatric conditions – BDD, depression, eating disorders – that may contraindicate a cosmetic procedure.

In the competitive marketplace of aesthetic medical treatment, where physicians from a range of medical specialties offer cosmetic procedures, it is unlikely that any physician currently requires new patients to undergo a mental health evaluation prior to treatment. Such a practice would likely drive patients to other practices almost instantaneously. More importantly, given the lack of reliable evidence suggesting a relationship between preoperative psychosocial status and postoperative outcomes (with perhaps the exception of BDD), recommendations for such routine evaluations is not warranted.²⁰ Rather, physicians who offer aesthetic procedures, like all medical professionals, should assess and screen for the presence of psychopathology as part of a medical history and completion of physical examination. Unfortunately, most physicians (or their delegates) likely skip this part of the assessment and, as a result, likely fail to identify patients who may exhibit symptoms of significant psychopathology or have a history of abuse or neglect that may impact their psychosocial functioning.

Specific questions asked during the initial consultation can be an effective way of identifying patients with mental health issues. These questions can help safeguard providers against patients who could become litigious or violent; it also provides an opportunity to direct patients to appropriate psychiatric treatment if needed. Patients should be informed that these questions are part of the practice's standard initial consultation procedures and are asked of all prospective patients. Such a statement can help reassure patients that they are not being "singled out" and may encourage an honest disclosure of information.

Psychiatric history and status

The assessment of the patients' psychiatric history and current status is a central part of the evaluation. Approximately 20% of patients who seek cosmetic surgery or minimally invasive procedures report using a psychiatric medication at the time of treatment.^{115,141} As mental health professionals frequently observe, patients who receive these medications from a primary care physician often do not experience complete relief from their symptoms. Thus, a psychopharmacologic

evaluation should be considered if symptoms do not appear to be well controlled. If a patient is in treatment with another mental health professional, the surgeon should contact this professional and, as appropriate, discuss the patient's appropriateness for treatment.

For patients with current symptoms of BDD or a history of psychiatric disorders or psychiatric hospitalization, a preoperative mental health evaluation is recommended before proceeding with surgery. If a patient discloses (s)he is currently receiving psychiatric or psychological treatment, the surgeon or staff should request permission to contact the patient's mental healthcare provider in order to discuss the appropriateness of surgery. Surgeons should be cautious about proceeding with surgery if the patient refuses to allow contact with their mental healthcare provider.

Motivations and expectations

The surgeon also should inquire about motivations and expectations for aesthetic treatment. In assessing motivations, the provider may want to ask, "When did you first think about changing your appearance?" Similarly, it may be instructive to ask, "What other things have you done to improve your appearance?" In addition to providing important clinical information, these questions also may reveal the presence of some obsessive or delusional thinking, as well as compulsive or bizarre behaviors, related to physical appearance. Some patients may report that they have tried several "do-it-yourself" treatments, such as non-FDA approved treatments, in an attempt to improve their appearance, many of which may be unhelpful and, in some cases, potentially dangerous.

Patients should be asked how romantic partners, family members, and close friends feel about the decision to change a physical feature. While these individuals likely influence patients' decision-making process, their role may not be as great as intuitively thought. For example, candidates for cosmetic breast augmentation surgery reported that their decision to seek surgery was influenced more by their own feelings about their appearance than it was influenced by the thoughts of their romantic partners. Nevertheless, patients who seek treatment specifically to please a current partner, or attract a new one, are thought to be less likely to be satisfied with their postoperative outcomes. Thus, the treatment provider should inquire about patients' general expectations about how the change in appearance, which may be rather subtle and potentially unnoticed by others, will influence their lives.

There is some evidence to suggest that individuals who undergo cosmetic procedures are seen as younger looking and more attractive. However, there is no evidence to suggest that aesthetic procedures directly impact interpersonal relationships. Therefore, patients should be reminded that it is impossible to predict how others will respond to their changed appearance. Some patients may find that few people notice the change in their appearance, while others may have the experience that everyone seems to notice them. While some patients may find this attention pleasurable, others may find it uncomfortable. To assess this issue, patients should be asked how they anticipate their lives will be different following treatment. The experience of unmet postoperative

expectations is another possible explanation of the relationship between cosmetic breast augmentation and suicide.¹²¹ Some women may present for breast augmentation surgery with unrealistic expectations about the effect that the procedure will have on their romantic relationships or daily functioning. When these expectations are not met, they may become despondent, depressed, and potentially suicidal.

Physical appearance and body image

Individuals presenting for an aesthetic treatment should be able to articulate specific concerns about their appearance that should be visible to the treatment provider with little effort. Patients who are markedly distressed about slight defects that are not readily visible may be suffering from BDD. The degree of emotional distress and impairment, rather than the specific nature of the defect, may be more accurate indicators of BDD in aesthetic medical patients.

Aesthetic medical treatment providers, and consulting mental health professionals, should be prepared to ask specific questions to assess for the presence of BDD. Individuals with nonexistent or minimal flaws who spend at least an hour a day preoccupied with perceived flaws, who experience resulting clinically significant distress or impairment in functioning, and who perform at least one associated repetitive behavior are believed to have BDD.

Patients who present with concerns about minimal or slight defects in appearance (e.g., asymmetry that would typically only be noticeable to a trained professional) should be carefully assessed. In cases where patients present with minimal or slight defects in appearance, the degree of distress they are reporting and the amount of functional impairment they are experiencing can help differentiate those with and without BDD. For example, a patient who is so concerned about a minimal or slight defect that (s)he refuses to attend school or leave home likely meets criteria for BDD. In contrast, a patient with a minimal defect who reports feeling self-conscious in some situations but is otherwise functioning well most likely does not have BDD.

Patients with BDD are often secretive about and ashamed of their concerns and the extent of their preoccupation and distress. In our experience, some patients purposely minimize their symptoms in the hope that the surgeon will not discover that they have BDD and refuse to operate. As discussed above, it is not uncommon for BDD to go undetected by aesthetic surgeons or dermatologists who offer cosmetic treatments. The majority of aesthetic surgeons and dermatological surgeons have reported that they have had the experience of operating on a patient only to recognize, during the postoperative course, that the patient had BDD.^{116,117}

There are a number of other behaviors that may suggest the presence of BDD or other significant psychopathology. In general, patients should be able to discuss specific appearance concerns that are readily observable. Patients who present with vague, nonspecific complaints (e.g., comments about being ugly or deformed, “my jaw just doesn’t look right”) may have BDD. Patients who express beliefs that other people are taking special notice of them because of their appearance “defect” may have BDD. Other individuals may make repeated requests for reassurance about the perceived flaw, which may signal the presence of BDD. Some patients with

BDD bring drawings to the consultation that detail how they would like to change their appearance or photos of celebrities to illustrate their idea of perfection; such behaviors may indicate the extensive amount of time they spend obsessing about their appearance. Patients who have had multiple procedures on the same body part yet still express dissatisfaction with treatment outcomes may have BDD. Those who have had many previous cosmetic procedures should be carefully queried about their satisfaction with the prior procedures, the nature of their appearance concerns, BDD symptoms, and expectations for treatment outcomes.

The degree and psychosocial consequences of dissatisfaction also should be assessed. Asking the patient about the amount of time spent thinking about a feature or the activities missed or avoided may indicate the degree of distress and impairment a person is experiencing and may help determine the presence of BDD. Self-report measures of BDD symptoms, such as the BDDQ, also may be helpful in this regard.

If the surgeon suspects that a patient has BDD, he/she is encouraged to inform the patient of their impressions and to provide some brief education about the disorder (e.g., “It sounds like you have a body image problem known as body dysmorphic disorder, a known and treatable condition”). We also recommend that surgeons inform patients with suspected BDD that they are concerned that the patient will be dissatisfied with the outcome of the surgery and that cosmetic procedures rarely help BDD symptoms, and can in fact make them worse. Then, patients should be briefly made aware that there are effective treatments for BDD, including psychiatric/psychological treatments, and referrals to a psychiatrist and/or psychologist can be made. It can be helpful to provide patients a list of local mental health providers with expertise in BDD or other body image problems and to convey to the patient that effective mental health treatments are available.

A major challenge in making such referrals is the poor or absent insight that is typical of BDD. Patients may resist the diagnosis because they believe that they truly are ugly. It can be helpful for surgeons to note that there is a mismatch between how people with BDD see themselves compared to how others see them, for reasons that are not well understood – that individuals with BDD see themselves as ugly or deformed, whereas other people do not see them this way. It is not helpful, however, to argue with the patient about how they look or to try to convince the patient that you are right and they are wrong, as this is likely to be ineffective. In our experience, it is more helpful to empathize with and underscore the patient’s distress and the impact of their appearance concerns on their daily lives (e.g., “I can see how worried you are about your jaw and how much it’s upsetting you and interfering with your life”); this approach can be helpful in encouraging patients to accept a mental health evaluation and treatment.

In general, it is best to be clear about why a referral to a mental health provider is being made (to get effective treatment for BDD) and not to promise that surgery will be performed after the psychiatric evaluation. It is best not to minimize the patient’s concern (e.g., “It’s all in your head”), provide reassurance that they look okay (unless the patient recognizes this to some degree themselves), or say something like “Well, I see a little something, but it’s not that bad”; these strategies are unlikely to be helpful and may even exacerbate the patient’s distress. Surgeons are also discouraged from

giving in to requests to perform minor procedures or to offer less invasive treatment options to appease the patient,³⁰ as in our experience patients may have a poor outcome following even minor interventions. Referrals to other surgeons are also discouraged, as this gives patients the implicit message that surgery may be helpful when in fact it appears unlikely to be.

Observing office behavior

Physicians and their staff should pay attention to patients' behavior in the office. Deviations from expected, typical behavior may reveal clues about BDD or other psychopathology. Demands for unusual appointment times (e.g., in the evening or early morning), repeated cancelling and rescheduling of appointments, excessive phone calls, angry or threatening demands to speak with the surgeon, or repeated reassurance-seeking from staff about their appearance may be indicative of BDD. Surgeons may be unaware of these behaviors, particularly if patients are "on their best behavior" during their consultation in hopes of convincing the surgeon to perform the desired procedure. Surgeons can consider asking patients to return for a follow-up consultation if the office staff raise concerns. A mental health evaluation is recommended if concerns about the patient's behavior persist.

General considerations

A mental health professional can be a valuable consultant to an aesthetic medicine practice. The mental health professional should have a good understanding of the psychological aspects of aesthetic medicine, as well as knowledge of disorders with a body image component, such as BDD and eating disorders. In most cases, the mental health professional will be called upon to assess a patient's psychological appropriateness prior to and for a given procedure. The mental health professional also may be asked to consult on the care of a patient postoperatively. This is most likely to occur in situations where the patient is dissatisfied with an objectively successful outcome or when the patient experiences a significant postoperative complication and is experiencing emotional distress.

Regardless of the circumstances, aesthetic surgery patients may react to a referral to a mental health professional with

anger and defensiveness, believing that they will only feel better if they look better. Others may assume that the medical professional assumes they are "crazy". Many will likely refuse to go to the consultation, which can provide indirect, confirmatory evidence that a patient is not psychologically appropriate for surgery. To increase the likelihood that the patient will accept the referral, it should be treated like a referral to any other health professional. The patient should be informed of the specific areas of concern and the reason for the referral. This information also should be shared with the mental health professional in advance of the consultation.

Conclusion

Interest in the psychological aspects of cosmetic medical procedures has grown in parallel to the overall popularity of the treatments. While early clinical reports from this literature suggested that most patients presented for treatment with some form of psychopathology, more contemporary and methodologically rigorous studies have identified few differences between individuals who seek cosmetic treatments and those who do not. Perhaps the most consistent difference is that those women and men who seek cosmetic treatments report higher levels of body image dissatisfaction. This dissatisfaction is believed to motivate the pursuit of treatment and improve following improvements in appearance.

Unfortunately, some individuals present for cosmetic treatment with extreme body image dissatisfaction. This dissatisfaction is a hallmark characteristic of both eating disorders as well as body dysmorphic disorder. Between 5% and 15% of persons who seek cosmetic treatments are believed to suffer with BDD; unfortunately, few experience improvements in their symptoms following treatment, leading to the belief that BDD is a likely contraindication to cosmetic treatment.

For these and other reasons, plastic surgeons and other physicians who offer cosmetic treatments are encouraged to evaluate the psychosocial functioning and status of new patients. Assessment of motivations and expectations for treatment, body image and appearance concerns, as well as psychosocial status and history can identify patients who may be inappropriate for treatment. Such assessment can also help to insure that the largest number of patients experience their physical as well as psychosocial goals for treatment.

In this paper and part one with the same title analyzing data from 100 consecutive secondary rhinoplasty patients, my co-author and I established a positive correlation between the degree of nasal deformity, the history of childhood abuse or neglect, the number of prior rhinoplasties, the number of other cosmetic surgeries, and satisfaction with the surgical outcome. Patients who originally had noses that they knew were normal but had surgery anyway (which defines body dysmorphic disorder) had also undergone the most rhinoplasties, the most other cosmetic surgeries, were the least likely to be satisfied with one corrective operation (in this series, 3%), and had the highest prevalence of childhood trauma (over 90%).
94. McFarlane AC, De Girolamo G. The nature of traumatic stressors. In: van der Kolk B, McFarlane AC, Weisaeth L, eds. *Traumatic Stress*. New York: Guilford Press; 2007:129–155. This chapter from van der Kolk's first landmark book details the effects of trauma upon

brain development, function, and memory. In doing so, it provides insight to the seemingly irrational behavior of surgeons' most unhappy patients, who are responding to triggers unappreciated by the surgeon.

 92. Constantian MB, Lin CP. Why some patients are unhappy, part two: relationship of nasal shape and trauma history to surgical success. *Plast Reconstr Surg*. 2014;134:836–851. In this paper and part one with the same title analyzing data from 100 consecutive secondary rhinoplasty patients, my co-author and I established a positive correlation between the degree of nasal deformity, the history of childhood abuse or neglect, the number of prior rhinoplasties, the number of other cosmetic surgeries, and satisfaction with the surgical outcome. Patients who originally had noses that they knew were normal but had surgery anyway (which defines body dysmorphic disorder) had also undergone the most rhinoplasties, the most other cosmetic surgeries, were the least likely to be satisfied with one corrective operation (in this series, 3%), and had the highest prevalence of childhood trauma (over 90%).

The role of ethics in plastic surgery

Phillip C. Haeck

SYNOPSIS

- Ethics as seen by professional associations.
- Ethical relationships with patients.
- The ethics of advertising.
- The role of ethics in the outpatient office.
- Ethics in the operating room.
- Ethical relations with other providers and third-party payers.
- The ethics of expert witness testimony.
- Summary.

The subject of ethics pervades the specialty of plastic surgery. Ethical decisions are highly prevalent in its practitioners yet few realize they confront these choices regularly, almost daily. Behaving in a morally responsible fashion, maintaining high personal codes of conduct, and remaining competent in operations are noncognitive functions for the vast majority of surgeons; it is deeply ingrained in the psyche. It also serves the surgeon well in presenting an overall highly regarded and deserved reputation amongst colleagues and the public.

Who to operate on and, more importantly, who not to operate on can in many instances be dilemmas that require moral choices. But many times the rationale is played out in the surgeon's subconscious, one more decision out of dozens made daily, with just a few moments to evaluate the alternatives. Plastic surgeons do not go home to their spouses every night and claim they made a number of highly ethical choices that day. Yet in reality the effects of not making the right choices can set up traps and entanglements. Breaching unwritten and written moral codes may bring consequences in this specialty. The harm may be done to others. The fallout is usually the surgeon's predicament.

Consider this common scenario. A patient consults the plastic surgeon for a rhinoplasty, complaining of poor breathing and an old fracture. She also doesn't like the shape of the

tip of her nose. She claims she has no money for any private payment of the fees involved. But she also claims to have over a half-dozen friends who want their noses changed and states she will take them to meet the surgeon on each of her subsequent visits. The surgeon agrees to charge her insurance company for the entire procedure, hoping in the end to capture more business from the friendly and social patient, deciding it is a justifiable prevarication. Is this an ethical dilemma?

The moral issues of this story become a web of further entanglement when the insurance company suspects it paid for a portion of the surgery that was cosmetic and not functional. A few months later the patient receives a denial of payment from the company for what they have determined is the cosmetic portion of her anesthesia charges, the facility fee and surgeon's fees. She is suddenly required to pay a sizable amount of money and in turn begs the surgeon to write off the balance since she still cannot afford to make up the difference.

Did the surgeon commit fraud? Was his decision to further his practice by committing a deception immoral? If he refuses to let the patient off the hook financially, will this affect his reputation with her friends who are by now signing up for their own surgery? Even if he made the very first decision that led to this predicament casually he cannot easily make this last choice without some degree of moral calculation.

Consider another situation. A 65-year-old uninsured diabetic is hit by a bus and suffers a compound tibia-fibula fracture and degloving injury of one-third of his lower leg. He is a smoker and is insulin-dependent. After the fracture is stabilized the plastic surgeon is asked to consult on the case for soft-tissue coverage of the sizable defect. Knowing that the zone of crush injury is extensive and there is compromised blood flow to the lower leg, the surgeon must decide if a long and expensive operation with a modest but very real chance of being unsuccessful is worth the effort and cost. With an amputation below the knee the chances this man will ambulate in a prosthesis are good, but not guaranteed. Will

prolonged recovery from a valiant limb salvage operation be the better choice? The surgeon knows he will not be reimbursed well for his efforts. His decision, if made on high standards, is based on what is right for the patient, not the surgeon.

These types of choices are encountered in similar situations on a daily basis by plastic surgeons all over the country. How one deals with these types of scenarios is multifactorial, complex and requires sophisticated decision trees. It is not immoral or unethical to say no in these situations.

Highly ethical persons have a well-developed internal moral code. They conduct themselves accordingly and believe that to do anything less would make them guilty of immorality. Contrast this with a sociopath who has no capacity for guilt, makes choices that he knows will deliberately harm others and then denies responsibility for the consequences. People living at the opposite extremes of this spectrum are rare. Most of us fall somewhere in between, the angel on one shoulder and the devil on the other.

Surgeons are themselves no different even though they have all supposedly taken the oath of Hippocrates to “above all else, do no harm”. The training of surgeons results in behavior that is consistent with the moral character of the role models the surgeon learned from, in both a positive effect and a negative one, sometimes full of awe, other times full of loathing. The behavioral end result of this training is a hybrid of choices, instincts, and internal codes that is rarely monolithic. More often the surgeon who has trained hard for a subspecialty designation is a complex, principled individual with a great capacity for a wide variety of mostly predictable and virtuous behaviors.

The specialty of medical ethics comprises a wide range of subjects that is considered valuable for physicians to consider and be knowledgeable about. It also takes into account the effects surgeons can have on society and vice versa. This includes controversial issues such as whether or not society should allow late-term abortions, death with dignity, or rationing of expensive treatments, to name a few. In general, the literature in medical ethics contains very little on the subject of plastic surgery.

In the lay literature, the ethics of having one's appearance altered is a somewhat more common, but still rare, subject. Feminists weigh in on this topic most frequently, as do PhD candidates in the fields of sociology and behavioral psychology.¹⁻³ Yet these dialogues do not take into account the possibility that the surgeon has high moral standing. Instead the plastic surgeon is cast as a villain, forcing his or her susceptible patients into paying more than they can afford for quite frivolous reasons. The patients are defined as foolishly chasing an impossible-to-obtain god-like appearance, involuntary victims of society's fascination with attractiveness. A further subtheme of these publications is the speculation that widespread alteration of homely persons into attractive ones will in the long term breed out common sense in our society.

The specialty journals in reconstructive or cosmetic surgery rarely, if ever, contain purely ethical articles of interest to the plastic surgeon.⁴⁻⁶ There are, for now, no ethical courses one can take at medical symposia, and forums on the subject of ethical plastic surgery are unheard of.

Yet the fact remains that ethical decisions are quite common in the lives of plastic surgeons, in some cases occurring even on a daily basis.

Ethics as seen by professional associations

The American Society of Plastic Surgeons (ASPS), the largest membership organization in the specialty, was formed in 1935. The association's attempt at a written Code of Ethics was first published in 1980. Members in good standing are expected to be familiar with this code and to adhere in their daily practice of surgery to the standards espoused within it. Failure to adhere to the guidelines can result in disciplinary action, including expulsion.

The expectations for ethical behavior on the part of members of the professional association are strongly worded and very specific. At times the code has been modified to meet new challenges such as those posed by the internet, charity raffles, and expert witness testimony. All realms of the specialty are covered within its dictums. The code also clearly spells out how a member will be dealt with if there is perceived to be a violation of the rules of the code.

Other members, patients, and lay persons can all lodge a written or verbal complaint with the ASPS Ethics Committee, stating what they think may be unethical behavior on the part of the member, actions that fall outside the proscriptions of the code. The member is then investigated by his or her peers and if it is decided that a violation did take place, the information is then passed along to the Judicial Council. The Council, comprised of members voted into that position, holds hearings to determine if sanctions should be placed on the member. Personal appearances before the Council are welcomed and the decisions made after a hearing are binding. Appeals of these decisions can be made to the Board of Trustees of the organization but are done infrequently. Plastic surgeons who are members of the American Society of Aesthetic Plastic Surgery (ASAPS) are subject to the same Code of Ethics and discipline. Members in good standing of both organizations may be elected to hold positions on the Ethics Committee and the Judicial Council for a period of 2–3 years.

Table 4.1 is a compilation of the data available from a review of the ASPS Ethics Committee's activities over the 4 years from 2006 to 2009.

While fewer complaints have been lodged lately, down to 81 in 2009 from 139 in 2006, the number of complaints that are reviewed after a committee investigation remained stable over this same period. Likewise the number of reviews that led to a hearing stayed at the same level, as did the number of hearings that resulted in disciplinary action.

Table 4.1 American Society of Plastic Surgeons Ethics Committee's activities, 2006–2009

Ethics complaints	2006	2007	2008	2009
New complaints	139	131	114	81
Complaints dismissed	101	77	54	36
Cases reviewed	38	54	60	45
Referred to Judicial Council	10	15	18	15
Cases disciplined	5	9	8	8
Complaints closed	153	129	108	84

Table 4.2 Average complaints by category per year, 2006–2009

Advertising	50
Medical board discipline	20
Contest	11
Standard of care	12
Expert witness testimony	10
Professional misconduct	6
Exorbitant fees	3
Criminal charges	2
Expert report	2
Total	116

Table 4.2 reveals the average number of complaints by category over the 4-year average. Advertising interpreted to violate the Code of Ethics has remained the complaint with the highest frequency over many years. The second highest category remains the investigation of those members who have been sanctioned by their state medical boards. The third category, unethical behavior while participating in a contest where the prize is free surgery, remains controversial. Some members feel that promoting themselves over nonmembers who are self-designated cosmetic surgeons is necessary to compete for potential patients and that this portion of the code is too restrictive. Still others feel it adequately reduces the number of violations of the code and reduces behavior that besmirches the reputation of all plastic surgeons. This controversy is unlikely to end soon.

Plastic surgeons overall have a highly visible position in the medical profession. Reactions to unethical behavior can thus be intense and scathing. For this reason members of the ASPS and ASAPS are reminded from time to time to review their Code of Ethics. While the vast majority of members will never in their careers be accused of violating it, pleading that you had no idea your actions were directly opposed to the body of rules for conduct in the code never works well as a defense when confronted by this system.

Ethical relationships with patients

In an ideal world plastic surgeons would only meet patients for consultations that were precisely matched to their skills, with the perfect indications for only the operations they preferred to perform. The surgeon would immediately comprehend the correct desires of the patient, infallibly interpreting that person's own unique ability to deal with a complication or a less than desirable result. The surgical results would always heal immediately with no complications. The adoring patient would then refer many more patients just like themselves.

In reality things are rarely clear and perfect. Patients fret about what they will look like after cosmetic surgery; they worry hopelessly before reconstructive surgery that they will still end up looking deformed and disfigured. They fritter away the surgeon's time with endless questions about whether or not they should have the surgery. Then they present impossible impediments to surgery scheduling and are often unrealistic about their recovery, postoperative pain, and activity

restrictions. In a busy, demanding practice, how surgeons take control of these situations, occasionally to their own advantage, can sometimes lead to unethical decision-making. Taking the high moral ground, while always the best choice, can sometimes seem impractical and intrusive when demands on the surgeon are almost overwhelming.

When a surgeon's compensation is determined solely by the number of surgeries he or she can perform in a week, a month and a year, operating on a person ill-suited to the surgery can possibly, perhaps eventually, occur. Some surgeons claim only to operate on patients with whom they feel comfortable. Obviously they have the luxury of dismissing patients they don't like and have a practice of truly elective procedures only. Being financially rewarded from performing surgery on people with unrealistic expectations, who may be ill-suited emotionally for the end result, is not the norm in this specialty. Yet it does occur, perhaps too often.

The consequences of this, an upset patient who abhors the result and threatens lawsuits or reports to the media, will in most cases lead to regret, the surgeon ruing the day he or she laid the scalpel to that person's skin. But it does not necessarily guarantee the surgeon has learned to be more careful from the experience.

In the training of plastic surgeons, being grilled over and over from the elder surgeon as to the correct indications for surgery is common. The master surgeon feels he or she is there to teach future surgeons the unwritten rules, the pitfalls of making the wrong choice, and the integrity required to succeed in the specialty. Once in practice, however, new surgeons no longer have to answer for their every action. The guidance for making the right, not the wrong, choice is up to them alone, and the consequences can lead to an unhappy patient, a profound effect on their reputation, disciplinary action or, most unfortunately, malpractice litigation.

So it is that surgeons are ultimately judged by the "standard of care", what a reasonably prudent surgeon would do with similar training in similar circumstances. Moral and ethical behavior is one facet of the standard of care.

Truly ethical surgeons choose their patients based on a thorough evaluation that includes many factors, compensation being the least important. Patients with unrealistic expectations or obsessive behavior are dismissed appropriately. Patients who need reconstruction are chosen on the surgeon's ability to match the correct operation to the problem. Patients with needs beyond the surgeon's own particular skills are referred to others who have more expertise in that area.

Society expects that conventional and virtuous surgeons spend time teaching their patients what their expectations should be both for the less-than-perfect result and for unfortunate but rare complications. The option to dismiss the surgeon or seek another one once patients know the risks and alternative treatments should always be allowed. This is accompanied by a disclosure of how much financial responsibility the patient must bear for reoperations when things do not go as planned and another operation is needed.

In reconstructive surgery, patients' ability to pay or the type of insurance coverage they have does not affect the ethical surgeon's decisions to operate. The complete lack of insurance is balanced by the ability to find some type of payment coverage through social services or simply accept a very reduced fee in exchange. The need for the operation should not be

Fig. 4.1 Unethical advertising – billboard photo: “two for one.”

altered by the compensation that will result, especially if it is little to nothing at all.

The ethics of advertising

Advertising was considered completely unethical for plastic surgeons well into the 1980s. A few who tried it were considered outlaws and often expelled from their national or state and local plastic surgery associations. Many felt it “cheapened the specialty” and that reputation was all that should be needed to attract more patients.

Along came the 1990s and the social attitudes of the specialty changed. Television discovered plastic surgery and shows like *Extreme Makeover* thrust plastic surgery into the homes of millions, making “mommy makeovers” a household word. But it was the internet that tore down the last bit of reluctance to make promotion a major part of the everyday practice of plastic surgery.

Advertising in the specialty, when done in good taste and without hyperbole, will now be around for a long time. Unfortunately unethical advertising, done in poor taste with mind-numbing self-promotion, is also here to stay (Fig. 4.1).

The ASPS Code of Ethics has been modified several times in the last dozen years to keep up with the changing relaxation of social mores to physician advertising. But complaints from members about other surgeons’ unethical promotions continue to rank as the most frequent complaints each year to the ASPS Ethics Committee (see Table 4.2).

Examples abound. Fig. 4.2 is exactly what the Code of Ethics was meant to prevent: a rather tacky approach that cheapens and sullies the specialty regardless of the origin. The public lumps all plastic surgeons into one category, whether they are Board-certified or self-designated.

Showing misleading before-and-after photos, then implying this to be a typical result that can be obtained by any patient, is considered unethical as well (see Fig. 4.2). In addition, the temptation to airbrush imperfections or scars out of the photos can be hard to resist when software applications

abound that make this an easy task. Any altering of before-and-after photos is considered by the ASPS ethics process to be false and misleading advertising, subject to sanctions.

Other behaviors considered to be unethical include the trading of surgery *quid pro quo* for media exposure in a high-profile person. Examples unfortunately exist of television figures such as news reporters undergoing surgical treatment in return for free testimonials about the surgeon, on air or at public appearances. While the media industry doesn’t consider this out of the ordinary, plastic surgery associations maintain that it is in fact unethical.

Fig. 4.2 Unethical advertising where a single image is used for both before and after figures through the magic of digital alterations.

The role of ethics in the outpatient office

Building and maintaining relationships with patients and staff can occupy a good deal of the plastic surgeon's time. The temptation to extend those relationships outside the office or the practice and outside a professional nature will always be present. Grateful patients wish to offer favors in exchange for their surgeon's success. Adoring staff members want to know more about what their boss is like outside the clinic. It is only natural for attractions such as these to take place. How the surgeon handles this can make him or her more successful, but can also lead to situations that can become unconventional, complicated, and entangling.

While it is not considered unethical to socialize with one's staff, establishing sexual relationships with staff and patients violates general standards for professional conduct, and can end with unfortunate consequences, including charges of sexual harassment or other civil charges. Lecherous behavior, physical advances, and the creation of a sexually harassing environment are grounds for dismissal from professional organizations, civil lawsuits, and can even at times be considered criminal in nature.

Conventional behavior sets limits on these situations. But the unique situation in plastic surgery, where the female patient may be both physically and emotionally exposed, can create powerful forces that test the limits of decency, honesty, and virtue in male plastic surgeons. To a lesser extent the opposite gender roles can also occur, as women are becoming plastic surgeons at record rates.

Personal standards of conduct vary tremendously in the specialty, but television shows depicting sleazy, illegal, and unconventional behavior by plastic surgeons may have some element of truth. The malevolent, licentious, and perverse personality in some surgeons may in fact be portrayed in these situations. Hopefully this will remain rare and only in the purview of television. Brazen behavior may eventually be reported to some type of authority. The potential personal damage that can be done in these situations by and to surgeons should be deplorable to all.

Attorneys experienced with workplace lawsuits always recommend that, if a romantic relationship develops between a patient and a single physician, the patient must be given the choice of terminating either the doctor-patient relationship or the personal relationship. If the first choice is made the patient should submit to being discharged from the surgeon's care to another physician. Likewise, if a romantic relationship arises with staff members it is considered ethical and wise to discontinue the employee-employer relationship immediately, though the evidence suggests this happens infrequently.

The plastic surgery practice with multiple physicians presents the possibility for competitive economic and unprofessional behaviors amongst surgeons and staff. Manipulation of the staff to hinder the success of partners or to direct more business to oneself is considered unethical. Hiding income from expense-sharing agreements, contributing to rumors and lies about other partners, and other obtrusive and malevolent behaviors towards them ignore the rules of decency and virtue.

Ethics in the operating room

The outcomes of any surgery depend on the correct application of principles, decisions, and treatments, all of which require multiple informed and decent choices. How the surgeon conducts himself, resisting the temptation to blame others and even the instruments when things do not go as planned, affects his reputation amongst staff and colleagues. Each correct or incorrect decision made during surgery can be a reflection of the character and mores of each surgeon.

Cutting corners for economic reasons, covering up mistakes, and delivering different outcomes than planned may be fundamental indications of a dishonest character. Surgery is not immune to the effects of personality flaws.

The analogy of the old fairy tale by Hans Christian Andersen, *The Emperor's New Clothes*, to the potential for deceitful behavior occasionally exhibited by plastic surgeons can be illustrative. In the story, the weaver promises to make the emperor a set of clothes invisible to those ignorant or unfit for their positions, completely fooling him into wearing nothing. It is a classic case of "mind over matter".

To the extent this can be applied to plastic surgery, the limited effects of some surgery may depend on the extent to which the surgeon built up the patient's expectations, knowing full well that the patient had paid for something possibly requiring more time and effort or that might have had a more clearly effective result. While this is rarely as brazen as in the old fairy tale, it can slip into various parts of surgery, especially with the more common use of treatment machines the patients know little about. The happiness of the patient depends on the expectations for beauty woven into the sales presentation by the surgeon. Results will vary of course.

Certain energy-dependent skin treatments whose effects take many months to be appreciated parallel this story. Is it dishonest to promise fewer wrinkles when it is known the effects won't be as plainly evident as other treatments or as a more expensive surgery? When the frequently pricey payments on the machine need to be met, the temptation to oversell it can be enormous. The ethical dilemma is not just to sign reluctant patients up but also then to deny that the outcome was less effective and did not meet their expectations.

Conventionally moral surgeons recognize this trap and avoid it, choosing to defer income for traditional effectiveness. Others, who might still consider themselves to have mainstream values, nonchalantly overlook the issues for the sake of keeping busy, building their reputation and impressing other surgeons with the size of the practice. Willful and malevolent deception may not be in the forefront; mostly it is hidden, buried in this specialty behind layers of complex situations. But it certainly exists in many forms.

Ethical relations with other providers and third-party payers

The ASPS Code of Ethics is very specific about the pitfalls in monetary relationships that can exist in referral networks. Brazen kickbacks for referring a patient for whom the surgeon will be rewarded financially are considered illegal in most states. Fee splitting is as well. With Medicare it can become a

federal offense. More subtle alignments and *quid pro quos* with the referring physician may not constitute civil violations but nonetheless should be considered carefully as a possible ethical violation before being carried out.

Correctly applying Current Procedural Terminology codes which accurately and adequately depict the procedure that was performed is presumed to be the norm in surgery. Yet constant tension with third-party payers over what can be interpreted as their unjustified decreased reimbursement for procedures requiring high levels of skills creates a negative attitude that can pervade the business side of the profession.

When it is assumed the insurance company “cheated” the surgeon on the last payment, the temptation to overbill the next procedure is difficult to resist. Is it justifiable to “unbundle” codes, upcode, and overbill when one knows that the insurance company has the upper hand anyway? Who is really harmed by this? It is situational ethics in play: the seemingly acceptable deception that is justified because everyone else, including the payers, is playing the same game.

Much has transpired over the past 5 years as several large insurance companies have been taken to court in class-action lawsuits for unlawful changes to the billings of physicians. Their reply is that fraudulent surgical billing is rampant and they have to protect their bottom line. The truth may lie somewhere in between. Nevertheless, the real world seems to forgive physicians tempted to push the envelope of honor and conduct for now, given the intense fiscal realities. Patients may abhor what they hear about hospital billing, but forgive their own surgeon if he seems honest and caring. The more personal this becomes, the less patients consider it greed if it seems to be in favor of a surgeon who did a successful procedure on them.

On the other hand, in university teaching hospitals, where an attending surgeon is expected to supervise the training of many residents, there were in the past submissions of surgeon’s fees for being in two places at once, or even not present at all. The explanation was that as a teaching surgeon the physician was ultimately responsible for all of the outcomes and therefore justified in receiving the compensation. Some well-publicized record fines from the Centers for Medicare and Medicaid in the last decade have led to very strict rules for supervision and billing. Unethical billing is now scrutinized more closely than ever and the plastic surgery team may not be an exception. Obtrusive rules may have constrained the system and possibly gone beyond reason. Unfortunately they now exist because of the past abuse of the system by a very few.

The ethics of expert witness testimony

As in other sections of this chapter, once again, the issues outlined in the ASPS Code of Ethics are applicable here as well. Usually one of the most frequent complaints brought against a surgeon by another member of the ASPS is for testifying either in deposition or at trial in a manner that can mislead the jury or simply be out and out contrived of false statements of fact. Many of these complaints center around the expert declaring that the standard of care was to do the surgery in a specific fashion. In fact, however, many surgeons may not adhere to those same principles and perform the surgery differently, but not necessarily outside the standard.

Condemning one way or the other as not in alignment with accepted principles when in fact it may very well be, can swing the jury or judge to rule against the other member. Regardless of the outcome the member who has a legitimate issue can submit the testimony he or she feels was false or misleading to the ASPS Ethics Committee who will review the situation and arrive at a conclusion.

The Code of Ethics is also very specific about the expert’s reasonable experience with the surgery that was performed. The phrase “recent and substantial experience” needed to be more carefully defined because of retired surgeons’ declarations of the standard of care when in fact they may have not performed any surgery, let alone the one in question, for over a decade. As the code is written now this means within the last 3 years. Testifying about a procedure the surgeon has not performed then in 4 or more years can be considered misleading testimony.

Overall, these issues became such frequent complaints that multiple other modifications to the Code sections on testifying have had to be made. This now includes a declaration that all experts may be asked to sign, certifying they will be truthful in their testimony. The submission of the signed statement is voluntary but can be used as evidence in the courtroom, especially when a plaintiff’s expert is another member of the ASPS and has been known to have made misleading statements in other trials.

The ethics of physical or chemical impairment

As surgeons age they need to maintain both their mental and physical health. When hand–eye coordination changes with health and age, who is to judge the standards for ethical patient care when results are substandard due to unmanaged tremors, slipping dexterity, declining eyesight and weakened coordination among other physical effects of aging? Most surgeons can recall a mentor or friend who carried on despite these subtle changes who perhaps should have heard the call to stop operating before it became an issue with detrimental results. Similarly, however, many can recall a mentor who carried on with no changes to his or her surgical skills well into their ninth decade.

Choudry⁷ did a systematic review of 62 studies that related medical knowledge and healthcare quality to years in practice and physician age. Some 52% of these showed decreasing performance with increasing years in practice for all outcomes assessed.

Institutions vary greatly in their standards for the aging surgeon, but when much of plastic surgery is carried out in one’s own office, there is little to no oversight or governing body to control these issues.

The demands of plastic surgery where tolerances for error are measured in millimeters cannot be compared to, say, one’s driving skills or golf game. Only when one becomes a danger to others on the road or the course will these freedoms be taken away.

So the ethics of aging and carrying on beyond a reasonable time to retire can become acute when others know the truth.

Plastic surgeons who are truly ethical will always question their results, their ability to learn and grow and their own quality of care. Warning signs that these questions are not

being dealt with truthfully or that the surgeon may need a reality check include increasing complications, decreasing patient satisfaction with their results of surgery and mounting malpractice cases in addition to all of the above.

Beyond that is the issue of the silent colleague who is witness to incompetent surgery or impairment. For surgeons there has always been the fear that “turning someone in”, especially someone who was at one time highly skilled, will result at some point in recriminations from other surgeons in the hospital for doing so, either overtly or more often covertly. Walking the thin line between wishing to act on an errant surgeon but finding such action too unsavory does no one any good. Alternatives, however, exist to this onerous task and the hospital itself is morally responsible to act, with channels for privilege restrictions being commonly used.

The specialty, however, frequently operates well outside of the discipline provided by hospital privileges, especially when one owns their own surgical suite and is subject to no higher authority. Sadly, then, the end of an era in some surgeons’ career has come when malpractice issues pile up and obtaining insurance becomes too costly to continue or even nonavailable. Why wait until this tragedy occurs?

Chemically impaired physicians exist in this specialty as well, since we often are second only to anesthesiologists in terms of access to narcotics, benzodiazepines and other such abused medications. The impaired surgeon typically has gone to great lengths to protect their covert use of both drugs and alcohol from colleagues; even those closest to the impaired surgeon in the same practice relationship are usually unaware of the extent of the problem. Respondents to a recent AMA study⁸ met diagnostic criteria for impairment at the rate of 12.9% of male physicians and 21.4% of female physicians.

What therefore is ethical for the plastic surgeon who finds out the truth about a colleague but has a sense that acting on it will cause more harm than good? Moral principles must then override all other consequences, financial resources and friendships.

When patient care is compromised by impairment we all have the duty to intervene whether we find it distasteful or frightening. Avoiding the truth is just as unethical as the act itself of abusing substances that are too readily available.

Summary

The practice of medicine is complex, requiring constant decisions, discussions, and testing. How this plays out in the daily

lives of plastic surgeons depends on their background, training, personal mores, and interpersonal skills. Unethical behavior can range from pushing the envelope in insurance coding and billing, all the way to fraud, sexual deviation, and the cover-up of surgical misadventures. It is a pervasive issue that can be seen as either business as usual or a moral stance always to behave ethically. Human nature being what it is, the give and play between highly ethical behaviors and the alternative will always be a part of the specialty.

Business principles for plastic surgeons

C. Scott Hultman

SYNOPSIS

- This chapter provides a broad overview of the essential principles that characterize what a business does and how a business does its work.
- The ability to apply business concepts is of paramount importance if plastic surgeons are to become and remain leaders in healthcare.
- Plastic surgeons should understand and use strategy, accounting, finance, economics, marketing, and operations to help guide decisions about their practice.
- Innovation, entrepreneurship, and human resource management are three areas where plastic surgeons can add value to their practice and distinguish themselves from their competition.

Introduction

"Make everything as simple as possible, but not simpler."

Albert Einstein

Not only is healthcare business, it is big business.

The healthcare-industrial complex incorporates multiple sectors to deliver health and depends on an expanding group of interdisciplinary teams, services, and institutions to achieve this value proposition. Business sectors involved in the delivery of healthcare include not only professionals such as doctors, nurses, and administrators, but also hospitals, nursing homes, and home healthcare groups; drug manufacturers and developers; manufacturers of medical equipment and instruments; diagnostic laboratories; biomedical researchers; and biotechnological entrepreneurs.

Current estimates by the Office of Economic Cooperation and Development place healthcare spending at 17.9% of the United States' gross domestic product, with that percentage expected to increase to 19.5% by 2017.¹ For every dollar spent in the US on healthcare, 31% goes to hospital services, 21% to physicians, 10% to pharmaceuticals, 6% to nursing homes, 4% to dental services, and 28% to other categories, such as

diagnostics laboratories, medical equipment, and medical devices. Of note, 7% of total spending is assigned to administrative overhead costs.

If healthcare provided by physicians is not business, then physicians are certainly surrounded by business; they must navigate a complex environment that is full of paradoxes, inefficiency, and bureaucracy. Unfortunately, physicians receive no formal education in business but must learn on the job, through mistakes and successes, often one patient and one business problem at a time. Although many critics argue that healthcare has been tainted by the intersection with big business, which places the bottom line at the top and undermines the physician-provider relationship, many other thought leaders contend that healthcare needs business, to help solve problems of inconsistent quality, rising costs, limited access to care, and disparities in outcomes. Indeed, business thinking and business processes are desperately needed to transform our current system, so that healthcare can be available to all people, at fair-market prices, to improve the health of our community.

Why should plastic surgeons care about the business of healthcare? From an individual perspective, every plastic surgeon must either run a business or be part of a business, if the surgeon's practice is to thrive, grow, change, and continue to provide high-quality care. Whether one works for oneself, for a hospital or health maintenance organization (HMO), for an academic institution, for a non-profit or non-governmental organization (NGO), for a free community clinic, or for an overseas volunteer mission trip, plastic surgeons are involved with organizations that utilize business principles and interface with business entities.

From a broader perspective, however, plastic surgeons are uniquely situated to serve as leaders of healthcare systems and healthcare businesses. Given our extensive training, our collaboration with multiple specialties, our diverse portfolio of services that we provide, our problem-solving skills, and our entrepreneurial spirit, plastic surgeons have the leadership skills, influence, and positioning within the healthcare system to effect real change. Just as the Greek word *plastikos*,

which means to shape or to mold, was chosen to describe what we do as surgeons, this word could also impart upon us the ability to shape or mold our systems of healthcare delivery.

The knowledge and application of business principles is of paramount importance if plastic surgeons are to become and remain leaders in healthcare. The purpose of this chapter is to provide a broad overview of the essential principles that characterize what a business does and how a business does its work. Each section offers a topical overview, and readers are strongly encouraged to explore in more depth the following components of this chapter:

1. Strategy
2. Accounting
3. Finance
4. Economics
5. Marketing
6. Operations
7. Innovation
8. Entrepreneurship
9. Sustainable enterprise
10. Human resource management
11. Legal and regulatory considerations
12. Negotiation
13. Ethics
14. Leadership

The end of each section will spotlight an “Idea Watch,” as a forum to present novel, emerging, and occasionally controversial topics related to business and healthcare. Featured topics will be drawn from cutting-edge articles published in the *Harvard Business Review*, with the goal of promoting further reflection, analysis, and inquiry by the reader.

Plastic surgeons, at the very least, must learn the language of business, to have meaningful interactions with hospital administrators, insurance carriers, salespeople, and marketing firms. Hopefully, though, plastic surgeons can utilize the principles of business to improve the care that we provide, and in the end, to transform the industry in which we practice our science, and our art.

Strategy

“Long-range planning does not deal with future decisions. It deals with the future of present decisions... Significant competitive advantage lies with those organizations and individuals who anticipate well in turbulent times.”

Peter F. Drucker

Competitive advantage begins and ends with strategy (Box 5.1). Nearly all of the components of business are affected by strategy, from finance to operations, from marketing to managing human capital, and therefore a review of business principles should commence with an understanding of how strategy guides decision-making within an organization.

Strategy can be characterized as the art of inducing your competitor to do something else, while you focus on doing what you do well. In more academic terms, strategy is the process of forming, implementing, and evaluating decisions that enable an organization to achieve its long-term goals.

Fig. 5.1 Strategy: Porter's 5-Forces model of competition. HMOs, health maintenance organizations; PPOs, preferred provider organizations.

Strategy is dictated by (and, in turn, can influence) the organization's mission, vision, and values, which serve as a foundation to guide policy, projects, and programs. Furthermore, strategy is about competing on differentiation – creating a value proposition – in which a firm provides the consumer with a product or service of greater quality or at less cost than its competitor, deliberately choosing a different set of activities to deliver a unique mix of outputs.

Before examining specific strategic principles, one should become familiar with how the business environment affects the flow of inputs to outputs, along the **supply chain**. Because value is added at various points along this process, the entire axis, from supplier to consumer, is called the **value chain**. Primary activities of the company, which include inbound logistics, operations, outbound logistics, marketing and sales, and ultimately customer service, each create value that manifests in the final product; these processes are guided by strategic priorities and are coordinated by support activities that include technological development, human resource management, and firm infrastructure.

The most established and respected model of the business environment is Michael Porter's **5-Forces model of competition** (Fig. 5.1).² Each industry contains: 1) previously established competitors; 2) the potential for new entrants; 3) the threat of substitute rivals, who often compete on price; 4) suppliers, who can have significant bargaining power; and 5) buyers, who create demand for the outputs. Understanding the environment of a specific industry, such as healthcare, can strengthen decision-making and help with strategic planning. For example, how should an academic plastic surgery practice respond to the influx of recently graduated residents into the community? How should the solo private practitioner attract new patients in a fixed market, when a group practice dominates the landscape? How should surgeons challenge scope of practice with non-surgeon physicians and non-physician providers? What is the optimal portfolio of services, specifically the mix of reconstructive surgery, cosmetic procedures, and skin care, to achieve the goals of the organization?

Once the dynamics and landscape of the business environment are defined, specific decisions can be made regarding change in operations, marketing, investment in new assets, alliances, or supply chain.³⁻⁵ Most mature industries, such as the automotive industry or the personal computer industry,

settle into a competitive scenario in which one firm dominates with 60% market share, while a second firm contains 30% of the market share, and the remaining competitors occupy 10%. Because of barriers to entry, new entrants may not be able to successfully compete, unless disruptive technology lowers production costs or the market shifts, due to cultural, social, economic, or political forces. In fact, significant competitive advantage is conferred to small, nimble firms that focus their product line or services and offer a unique selling proposition, to a targeted segment of the market. When executed correctly, this activity, termed “**judo strategy**,” has the power to undermine dominant businesses and increase market share substantially.

A major limitation of competitive strategy is that most efforts deal with gaining a larger portion of a fixed market or attracting new customers via the “rising tide” of a slowly growing market. If companies in search of sustained, profitable growth compete with multiple rivals, then differentiation becomes difficult, price wars may ensue, and the total profit pool shrinks. Instead, companies may pursue a “**blue ocean strategy**,” in which uncontested but related market space is discovered, rendering rivals obsolete and generating new demand. Previous “settlers” will “migrate” to this new market space and become “pioneers.” Apple has done this over and over with the personal computer market, introducing new devices that expand the functionality of their operating system and hardware, evidenced by the transition from desktop to laptop to iPhone to iPad.

True value innovation comes when a company jumps out of their industry and creates an entirely new market, often in a different industry.^{6,7} This foray into uncharted territory, which is referred to as “**white space**,” typically occurs when a company develops a disruptive technology that permits the use of core competencies to produce a radically different product or service. Apple was successful in capturing the dominant position in the digital music market by designing and offering iTunes, despite being a computer company. Inherent to this success was the fact that Apple also changed the business model for purchasing music; consumers could buy singles or albums, listen to samples, and of course, use the website for free. As the music industry shifts again, from purchasing content to subscription services as a major revenue model, Apple is determined to remain the dominant player. The acquisition of the Beats music platform will allow Apple to compete with Pandora and Spotify, but also serve to stream video content for gaming and on-demand viewing of television and film.

In summary, strategy involves the following steps:

1. **Industry analysis** – assess industry profitability today and tomorrow
2. **Positioning** – identify sources of competitive advantage
3. **Competitor analysis** – study current competitors, future entrants, and substitutes
4. **Assessment of current strategy** – predict effectiveness and sustainability
5. **Option generation** – search for new customers, new segments, new markets
6. **Development of capabilities** – planning now for future opportunities
7. **Refining strategy** – assess uniqueness, trade-offs, compatibility with vision and values

BOX 5.1 Idea watch: strategy

Reference: Raynor ME, Ahmed M. Three rules for making a company truly great. *Harvard Business Review*. 2013;91:108–117.⁶⁵

How do great companies make great strategic choices? The authors studied 25,453 businesses, operating over a 44-year period, and identified several hundred that had exceptional, sustained performance. The decisions that allowed certain companies, like IBM, 3M, Merck, and Medtronic, to outperform their peers, followed three simple rules:

- Better before cheaper (compete on differentiators other than price)
- Revenue before cost (prioritize increasing revenue over reducing costs)
- There are no other rules (to change anything you must follow the first two rules)

These rules did not dictate specific behavior, or even general strategies, but instead served as foundational concepts, or guides, when making strategic decisions about acquisitions, diversification, resource allocation, and pricing. Competitive positions built on greater differentiation through brand, style, or reliability were more likely to drive exceptional performance than positions built on lower prices.

Accounting

“Nowadays, people know the price of everything and the value of nothing.”

Oscar Wilde

Business management must be based upon a common language that is used to objectively communicate information related to the quantitative metrics of an organization. That language is accounting (Box 5.2). This section will review the tools that accountants use to assess the financial health of a business: **income statement**, **balance sheet**, **summary of cash flows**, and **financial ratios**.^{8–10} The nuances of accounting are beyond the scope of this overview, but healthcare providers must have a basic comprehension of these instruments and how they represent the financial standing of their practice, their hospital, and their healthcare system. Furthermore, these instruments are used in budgeting to construct pro forma predictions of future performance.

The field of accounting is governed by generally accepted accounting principles, also known as **GAAP**, which are rules used to prepare, present, and report financial statements for various entities, such as non-profit organizations, publicly-traded companies, and privately-held firms. Although the government does not set these standards, the US Securities and Exchange Commission does require that public firms follow these rules. Managerial accounting, which is used to allocate cost and assign overhead, does not follow GAAP and is dependent upon institutional culture and practice.

Income statement

The income statement, also known as the profit/loss statement, describes financial transactions within a defined period of time, which may be quarterly or annually. Revenue refers to the gross income that a company receives from normal

business activities, typically the sales of goods or services, but may also include rent, dividends, or royalties. In accrual accounting, revenue occurs at the time of the transaction, not when receipts are collected. Net income is expressed as a profit or loss, after deducting expenses, which usually include operating expenses (cost of goods sold, variable overhead expenses), depreciation of assets and amortization of leases, fixed overhead (selling and administrative expenses, research and development), interest expenses, and taxes.

Revenue

less Operating costs

= Gross profit

less Fixed overhead

less Depreciation (assets) and amortization (leases)

= Operating income (EBIT)

less Interest expenses

= Pre-tax income

less Income taxes

= Net income

Balance sheet

The balance sheet is a snapshot of what the company owns and owes, at a single point in time. On one hand, the balance sheet summarizes the cumulative impact of all transactions, but the balance sheet does not provide much useful information on the operational performance of the firm. The net worth of the company, referred to as owner's equity, is defined as the difference between the assets and the liabilities.

Equity = Assets – Liabilities

However, balance sheets usually frame this relationship slightly differently, but again, the following equation must always balance:

$$\text{Assets} = \text{Liabilities} + \text{Equity}$$

or

$$\text{Assets} = \text{Debt} + \text{Equity}$$

The actual worth of a company, the equity, is difficult to ascertain, but one method to calculate value is market capitalization, which is (share price) $\times$ (shares outstanding); this represents the public consensus of the value of the firm's equity.

Assets are defined as resources with probable future economic benefit, obtained or controlled by the entity, as a result of past transactions, that are expected to contribute to positive net cash flows. Examples of assets include cash and cash equivalents (pre-paid expenses, bonds, stock), accounts receivable (the money that is owed but has not been collected), inventory (raw materials, work-in-process, and finished goods), property/plant/equipment (purchase price less depreciation), goodwill (intangible value of brand), and intellectual property.

Liabilities refer to what a company owes, or from a different perspective, how the assets were obtained. Liabilities

include short-term loans (credit lines) current portion of long-term debt, accounts payable (the money a company owes its vendors), and long-term debt.

Owners' equity – the difference between assets and liabilities – can be allocated into several categories: preferred shares (which usually receive periodic dividends), common stock, and retained earnings (accumulated earnings that have been reinvested into the business, instead of being distributed as dividends).

Summary of cash flows

An assessment of a company's cash flows is critical in determining the financial viability of the firm, because profit is NOT the same as cash. This disconnect is due to multiple reasons: 1) cash may be coming in from investors or loans; 2) revenue is booked at time of sale, not collection; 3) expenses are matched to revenue, not when they are actually paid; and 4) capital expenditures do not count against profit (because only the depreciation is charged against revenue) but require cash or debt to pay for the assets. As a result of this discrepancy between when a good or service is provided and when cash is exchanged, following the flow of cash can be very complicated. Fortunately, we have accountants. For mature, stable, and well-managed companies, cash flow does approximate net profit. But for younger, growing, and poorly-managed companies, profit can occur without gaining cash (resulting in bankruptcy, because bills cannot be paid) or cash can accrue without being profitable (which bodes poorly for long-term success, if expenses cannot be controlled).

Overall cash flows are further subdivided into three categories – operations, investing, and financing – based upon the conduit for the flow. Cash flows from operating activities (CFO) indicate how much cash was generated from operations: selling goods and services. Cash flows from investing activities (CFI) indicate how much cash the company spent (or received) from buying and selling businesses, property, plant, and equipment. Finally, cash flows from financing activities (CFF) indicate how much cash the firm borrowed, received from selling stock, or used to pay down debt or repurchase stock.

Total cash flow represents the true flow of money through a firm and is a composite of the operations, investing, and financing, represented by the following equation:

$$\text{Total cash flow} = \text{CFO} + \text{CFI} + \text{CFF}$$

Many financial analysts believe that total cash flow myopically focuses on earnings while ignoring "real" cash that a firm generates and retains for future investments. Therefore, another measure of the ability of a firm to create value is free cash flow (FCF), which is defined numerically as:

$$\text{Free cash flow} = \text{CFO} - \text{capital expenditures}$$

or alternatively:

$$\text{Free cash flow} = \text{net income} + \text{amortization} + \text{depreciation} - \text{change in working capital} - \text{capital expenditures}$$

In other words, free cash flow represents the total cash that a company is able to generate after laying out the funds required

to maintain or grow its asset base. FCF is very important to investors because this allows a firm to pursue opportunities that increase shareholder value. This is the best source of capital for development of new products and services, acquiring new companies, paying stock dividends, and reducing debt. Cash really is king, and this is why.

Financial ratios

Because companies even within a single industry can vary in size and maturity, such instruments as the income statement, balance sheet, and summary of cash flows may not permit a valid comparison of those companies. Instead, financial ratios – the numerical relationship between two categories – can provide powerful insight into the financial health of a company. Jonathan Swift observed that “vision is the art of seeing what is invisible to others,” and financial ratios provide that vision.

Four types of ratios help managers and stakeholders analyze a company’s performance: profitability, leverage, liquidity, and efficiency. These ratios can be used to follow the performance of a firm over time or to compare several firms across related industries.

Profitability ratios

Gross margin = gross profit/revenue

Operating margin = operating profit/revenue

Net margin = net profit/revenue

Return on assets = net profit/total assets
= (net income/revenue) × (revenue/assets)

Return on equity = net profit/shareholders’ equity

Contribution margin = revenue – variable direct costs
(technically not a ratio, but loved by CFOs everywhere)

Leverage ratios

Debt-to-equity ratio = total liabilities/shareholders’ equity

Interest coverage = operating profit/annual interest charges

Liquidity ratios

Current ratio = current assets/current liabilities

Quick ratio = (current assets – inventory)/current liabilities

Efficiency ratios

Days in inventory = average inventory /
(cost of goods sold [COGS]/day)

Inventory turns = 360/days in inventory

Days sales outstanding = accounts receivable/(revenue/day)

Days payable outstanding = accounts payable/(COGS/day)

property, plant, equipment (PPE) turnover = revenue/PPE

Total asset turnover = revenue/total assets

BOX 5.2 Idea watch: accounting

Reference: Kaplan RS, Porter ME. How to solve the cost crisis in health care. *Harvard Business Review*. 2011;89:46–64.⁶⁶

Stephen Kaplan, who engineered the concept of time-driven, activity-based costing, collaborated with Michael Porter, who introduced the idea of the value creation to supply chain theory, to develop a new model for determining the true cost of providing healthcare.

In the process, they identified 3 myths that needed to be challenged: 1) charges are a good surrogate for provider costs; 2) hospital overhead costs are too complex to allocate accurately; and 3) most healthcare costs are fixed. Kaplan and Porter proposed methodology to calculate the total cost of patient care, based on blending the cost of resources needed to provide care, the time needed to provide that care, and the utilization and capacity of that resource. By using sophisticated managerial accounting, they discovered several opportunities to improve value:

- Eliminate unnecessary process variations and processes that don’t add value
- Improve resource capacity utilization
- Deliver the right processes at the right location
- Match clinical skills to the process
- Speed up cycle time
- Optimize over the full cycle of care

The remedy to the cost crisis does not require breakthroughs in medical science or new governmental regulation, but rather improved ways to accurately measure costs and compare them with outcomes. Educating and engaging all members of the healthcare team, through process mapping of patient care delivery, has the potential to reduce costs while improving outcomes.

Finance

“Markets are constantly in a state of uncertainty and flux and money is made by discounting the obvious and betting on the unexpected.”

George Soros

The goal of finance (Box 5.3) is to maximize corporate value while minimizing the firm’s financial risks.¹¹ If accounting is the language and grammar of business, then finance is a combination of poetry and theoretical physics, with some rock ‘n’ roll added to keep the mix interesting. The central thesis of finance is that risk can be managed successfully, in such a way that wealth is created, by combining the variables of cash, assets, supply chain, and human capital, to produce a good or service that is more valuable than the cost of production. The consumer, however, is the final arbiter who decides if the good or service is more valuable than the cost of the inputs, and if the output is more valuable than the price the consumer is willing to pay. If so, the consumer exchanges money for the good or service.

Risk can be measured statistically and therefore, given assumptions that are known with certainty, the outcome of decision-making can be predicted with specific probability. Thus, the decision to make an investment in a new piece of equipment, a new employee, a new product line, or to purchase another company, can be made with a certain level of confidence. However, when some variables are

unknown (ambiguity) or when no variables are known (true uncertainty), sound financial management may not be possible, to the point that flipping a coin may provide more insight regarding outcomes.

This section will introduce common tools used by financial managers when analyzing a financial scenario, to determine go/no-go decisions about acquiring and allocating assets. While understanding the mechanics of such calculations is not essential, understanding the logic behind the decision-making is critical, as well as understanding the significance of the results. We will review the following concepts: Time value of money, opportunity cost, net present value (NPV), discounted cash flows (DCF), weighted average cost of capital (WACC) and the hurdle rate, return on investment (ROI), and internal rate of return (IRR).

Time value of money

Money increases in value over time, and such appreciation is actually logarithmic (although it takes a while to get going!). Even Einstein conceded, "The most powerful force in the universe is compound interest." Essentially, a dollar today is worth a slightly more tomorrow and a lot more in ten years. A dollar invested in a money market account with an annual return of 2% will yield 2 pennies next year, increasing the value of this investment to \$1.02, which is future value of today's dollar. The formula for the time value of money is:

$$\text{Present value (PV)} = \text{future value} / (1 + \text{interest rate})^{\# \text{ of periods}}$$

Why does money have a time value? Economists attribute this to two factors: postponement of consumption and expectations of inflation. Interest rates are a hedge against this type of depreciation. As risk of an investment increases, then the reward to the investor needs to increase, to convince the investor to part with one dollar today, in hopes of having possibly \$1.20 next year (which would be a 20% return). The actual rate that money can appreciate is determined by multiple factors, such as the risk of the specific investment, the performance of the stock market, the return on US Treasury bonds, and the monetary policy established by the Federal Reserve, which sets the overnight lending rates to commercial markets.

Consequently, obtaining capital costs money. If one borrows money from the bank, this loan creates risk for that institution, so the bank will need to collect more money from the borrower, when the debt is repaid, at some point in the future. But here is the catch: banks need to charge not only for the time value of money, which is their expected rate of return (also called the discount rate), but the bank must also hedge against your riskiness as a borrower, driving up the cost of capital and increasing the interest rate that you must pay. In fact, if the bank can make a safer investment, with a possibly higher rate of return, then the bank should not pursue the loan.

Opportunity cost

When considering a new project or purchasing a piece of equipment, one should proceed if the intrinsic value of the asset equals or exceeds its cost. What one must also consider, though, is the opportunity cost of tying up precious time,

money, and energy in that project or asset, when those resources could be invested elsewhere. The definition of opportunity cost is the potential benefit forgone from not following the financially optimal course of action. Rather than thinking in yes/no parameters, the investor should make either/or decisions, searching for other opportunities, until he or she can compare the proposed course of action with the next best alternative. In the world of surgery, where most of physician revenue is generated from procedures, any activity that takes the surgeon out of the operating room should be carefully compared to what the surgeon could accomplish by staying in the OR.

Net present value (NPV) and discounted cash flows (DCF)

The decision to pursue a project, when economic considerations are important, involves determining the net present value of that opportunity. NPV is calculated by adding a time-series of cash flows, both incoming and outgoing, that the project is expected to produce, over a series of future periods. This calculation would include the initial cost of purchasing the asset, at DCF_0 , plus the anticipated revenue that the asset would generate, from DCF_1 to DCF_n . Each future cash flow must be discounted back to its present value.

$$NPV_{0-n} = DCF_0 + DCF_1 + DCF_2 + \dots + DCF_n$$

where n = number of periods

If the NPV is >0 , then the investment would add value to the firm, and the project may be accepted. If the NPV is <0 , then the investment would subtract value from the firm, and the project should be rejected. The discount rate selected is often the firm's weighted average cost of capital (WACC), which blends the cost of debt (borrowing money) with the cost of equity (shareholders' expected returns on their stock). Another approach in selecting the appropriate discount rate is to determine the rate that another investment would yield, if this capital were used in a different project. This required rate of return is often referred to as the hurdle rate, which is higher for riskier projects and lower for safer ones. The hurdle rate represents the expected rate of return for risk-free projects (tied to the US Treasury bill) plus the potential rate of return for risky projects.

Return on investment (ROI)

After one has projected future cash flows for an investment, how can one evaluate these future cash flows, in terms of the value of this investment? Several approaches are helpful in deciding the potential value of future ventures and in retrospectively examining the actual value of past ventures. These methodologies include: formal ROI or yield, the payback method, the internal rate of return (IRR), and the NPV/DCF model. The most rigorous and powerful technique is NPV/DCF analysis, but limitations include multiple assumptions regarding future cash flows, selecting the appropriate discount rate, and complexity of the calculation. As a result, predictions using NPV tend to be conservative, but at least they incorporate the time value of money, so that the investor can make decisions based on the value of today's dollars.

A much simpler approach to calculating ROI is yield, which is represented by the following formula:

$$\text{Yield} = (\text{gain from investment} - \text{cost of investment}) / \text{cost of investment}$$

Yield, however, is expressed as a percentage, and therefore gives little information about the magnitude of the value of the investment. Furthermore, yield can be easily manipulated by using varied metrics to define “gain” and “cost.” Yield is helpful when comparing similar products or services, within a market or industry.

The payback method, which measures the time required for the cash flow from the project to pay for the original investment, is also quite popular with mid-level managers, who need to justify the purchase of capital equipment and predict time to break-even.

$$\text{Payback time} = \text{cost of investment} / \text{annual cash flow}$$

What payback period does not take into account is depreciation of the equipment, useful lifespan of the asset, and residual value of the asset at the end of the period. Furthermore, cash flows for a project or asset usually change from year to year, and therefore the payback period only estimates when the project or asset reaches break-even. If the useful life of the investment is greater than the payback time, then the investment should be pursued, at least for financial reasons.

Another technique used to assess ROI is the internal rate of return, or IRR. Instead of assuming a particular discount rate for an investment and calculating the NPV, the IRR method determines the actual return projected by the cash flows. The IRR is then compared with the firm’s hurdle rate,

which may vary for different projects, depending upon the risk, the time horizon for the returns, and the cost of capital for the firm or WACC. Another way of understanding this method is that IRR represents the hurdle rate necessary to make NPV = 0. Problems with using IRR include not quantifying the overall value of the project, as well as how long the company can anticipate the length of the return. Nevertheless, IRR, payback method, and yield are helpful when communicating potential ROI to stakeholders, because of their simplicity and ease of understanding.

Economics

“Economists are about as useful as astrologers in predicting the future (and, like astrologers, they never let failure on one occasion diminish certitude on the next).”

Arthur Schlesinger, Jr.

The sheer enormity of the field of economics prohibits a detailed review in this setting, but nevertheless, key concepts can be outlined. The entire discipline ranges from macroeconomics to microeconomics, from normative economics to behavioral economics, from heterodox economics to game theory (Box 5.4).

Like other branches of economics, healthcare economics deals with decision-making in the setting of uncertainty, limited resources, and variable demand.^{12–15} However, healthcare economics is distinctly different from other branches of economics, because healthcare is an industry that includes extensive government intervention and regulation; asymmetry of information between provider, patient, and payer; lack of precise metrics, with regard to patient outcomes; and considerable externalities, which are the downstream effects on other entities, outside of the healthcare system.

Demand for a good or service is based upon a buyer’s willingness to pay, which in turn is influenced by the buyer’s tastes or needs, the consumer’s income or wealth, and the availability of substitute and complementary goods. Demand curves can then be constructed to describe an individual’s or a population’s willingness to purchase: as price increases, demand decreases. Price elasticity represents the change in quantity demanded as a function in change of price and is crucial to the way that markets adjust. Mathematically, this relationship can be expressed as:

$$E_d = \text{delta } Q / \text{delta } P$$

where E_d is the coefficient for the price elasticity of demand

(Although E_d is almost always negative, economists typically use the absolute value of E_d , making this a positive number)

Q = quantity of good or service

P = price of good or service

Elasticity coefficients can be interpreted as follows:

$E_d = 0$ perfectly inelastic demand

$-1 < E_d < 0$ relatively inelastic demand

$E_d = -1$ unitary elasticity

$E_d < -1$ elastic demand

$E_d = -1/0$ perfectly elastic demand

BOX 5.3 Idea watch: finance

Reference: McGrath RG. Transient advantage: strategy for turbulent times. *Harvard Business Review*. 2013;91:62–70.⁶⁷

Given the volatility of the economic markets over most of the 21st century, the previous dogma that strategy consists of establishing a unique competitive position, sustained for long periods of time, may no longer be relevant for many businesses. In the age of information, **transient advantage** may be the new normal. Businesses must learn to launch new strategic initiatives, again and again, based on a new set of operational capabilities. Just like a diversified portfolio of assets may hedge against risk, a portfolio of advantages that can be quickly built, and quickly abandoned, may improve the financial position of the company, by maintaining multiple revenue streams that result in combined net positive cash flows.

McGrath warns that businesses operating in a high-velocity setting will need to avoid traps previously viewed as advantages: first-mover, total quality management, white space positioning, and incremental innovation. Instead, companies should consider the following shifts:

- Think about arenas, not industries
- Set broad themes, and then let people experiment
- Adopt metrics that support entrepreneurial growth
- Focus on experiences and solutions to problems
- Build strong relationships and networks
- Avoid brutal restructuring; learn healthy disengagement
- Get systematic about early stage innovation
- Experiment, iterate, learn.

Goods or services with close substitutes, such as Botox® and Dysport®, have a flat, elastic curve, in which small changes in price produce large changes in demand. Other goods and services may have steep, inelastic demand curves, in which large changes in price may have minimal effects on demand; this is the case for necessities with few substitutes, some luxury items, and products with intense brand loyalty. Price elasticity for a given good or service may also vary, based upon the specific segment of the market targeted, and may be influenced by macroeconomic forces. When the purchaser does not directly pay for the good consumed or the service provided, such as a patient whose surgery is paid for by third-party insurance, price elasticity is likely to be relatively inelastic. Adding a copay or deductible transfers some of the cost to the consumer and increases the elasticity of demand for healthcare.

Supply of a good or service depends on a firm's short-term and long-run strategic goals. Decisions about supply are based initially on marginal costs, which vary with level of production. As production increases, so do marginal costs. However, average fixed costs decrease with increasing volume. These curves are combined to produce a U-shaped curve of average total cost, the nadir of which is the lowest price that the firm can charge and break even. A company can offer a good or service, as long as the market price remains above the average total costs. An aggregate market supply curve demonstrates that as price increases, more firms are willing and able to produce outputs.

Market equilibrium occurs when the supply and demand forces adjust to a price and quantity that satisfy both producers and consumers. Markets will move in predictable ways, based upon changes in supply and demand. Increased supply causes the equilibrium price to fall and the equilibrium quantity to increase. Conversely, new demand for a product or service will cause the equilibrium price to rise, with a subsequent increase in the equilibrium quantity.

Real markets, however, are messy and may behave in ways that only approach these rules. For these economic models to work, markets must have perfect competition, in which products are identical, sellers and buyers do not engage in strategic manipulation of supply and demand, players make rational choices, entry and exit barriers are non-existent, and participants are fully informed. Such a market does not exist. Predicting how economic forces shape the healthcare market is a considerable challenge, given that such competition is far from perfect.

Firms can gain strategic advantage, then, by exploiting the inefficiencies of the market. Ethical approaches include product differentiation, segmentation of the market, responding to new cultural, social, and political shifts, and using technology and innovation to create new value propositions. Unethical tactics would involve maintaining an asymmetry of information between consumer and producer, taking advantage of irrational decision-making, artificially creating demand or limiting supply, collusion with other players, and creating impassable barriers of entry for new participants. In the healthcare industry, providers must remain cognizant of these opportunities – both ethical and unethical – and maintain a level of responsibility that ensures professionalism at all times.

In summary, markets strive for equilibrium, but adjustments in supply and demand may not lead to productive efficiency, which by itself is not a guarantee of the fair

BOX 5.4 Idea watch: economics

Reference: Kaplan RS, Porter ME. Motivating salespeople: what really works. *Harvard Business Review*. 2011;90:71–75.⁶⁸

How do we improve the productivity of our employees? In healthcare, providers are expected to see more patients, improve quality of care, and optimize patient satisfaction, often with reduced resources. Fundamentally, incentivizing physicians, nurses, and therapists is a microeconomic problem, in which incentives should be aligned with performance to influence behavior. Laggards, Core Performers, and Stars each respond to different rewards, and therefore compensation plans should be structured differently to induce a higher level of productivity. Companies that structure their incentive plans based on these differences will realize better results across the performance curve:

Motivating Laggards

- Recognize, first, that this group is heterogeneous and can include new hires, complacent senior providers, and people who are just less talented than their colleagues; one size does not fit all
- Introduce more frequent, pace-setting bonuses
- Create natural, cultural, and program-specific social pressures

Motivating Core Performers

- Establish multi-tier targets for productivity
- Have sales or performance contests with awards that vary in nature and value

Motivating Stars

- Avoid ceilings on pay; controlling costs also encourages the stars to quit working
- Develop super-achievement commission rates.

distribution of wealth in society. A final quandary to ponder: not all of the costs and benefits of a transaction accrue to the buyer and the seller. These externalities – downstream effects on society – may be beneficial (new technology that extends life), but are too often detrimental (production of medical waste products). How can we incorporate these externalities into our decision-making, so that we increase the total social value of our actions?

Marketing

“Good companies will meet needs; great companies will create markets.”

Philip Kotler

Business could not exist without the customer, and marketing is the process that enables business to connect with the customer (Box 5.5).^{16,17} Marketing strategy identifies, attracts, satisfies, and retains customers. Seeking to build more than a single exchange between the producer and the consumer (or in healthcare, the provider and the patient), marketing is first and foremost driven by customer needs and desires. The ideal approach in marketing is initially to understand the customers in the context of their environment, which includes not only assessment of market size but also competitive forces, barriers to entry, and market structure. Next, marketing seeks to develop a specific product or service offering, based upon

anticipated customer needs that may or may not be adequately met, or may not even be appreciated. Finally, marketing strives to deliver customer value, in the form of price point, quality, and distribution.

Although marketing strategy has been often oversimplified by focusing on the “4Ps” – **product, price, promotion, place-ment** – this is a good starting point for our review. Product refers to the characteristics and defining features of a good or service. Price is determined by factoring in cost of production with what additional value can be extracted by the producer, based upon value-added features and the demand for the good or service. Calculating break-even volume is important to determine if a pricing strategy is reasonable. The formula for finding out how many units a company must sell, so that its costs are covered, is represented as follows:

$$\text{Break-even unit volume} = \frac{\text{fixed costs/}}{(\text{sales price} - \text{variable costs})}$$

To achieve a specific profit target, the formula can be modified as follows:

$$\text{Volume} = \frac{(\text{fixed costs} + \text{total profit})/}{(\text{sales price} - \text{variable costs})}$$

Promotion involves the channels that will be necessary through which the company can communicate its message and may involve advertising, use of a sales force, or incentives (bundled pricing, discounts, rewards, and frequent buyer benefits, for example). Placement is arguably the most important of these variables; marketing experts segment a general market to determine what types of people (young vs old, male vs female, high income vs low income) desire what types of products. Segmentation allows for better allocation of a company's finite resources, enables the firm to target specific high-yield groups, and improves positioning of the product for higher market penetration. In fact, a company can offer related but slightly different products if marketing research demonstrates that multiple segments have slightly different needs. Instead of pursuing a one-size-fits-all philosophy and missing segments of the market, a firm can employ marketing analysis to justify, with confidence, multiple offerings of related products.

Over the past two decades, in which consumers have been empowered by the internet (online auctions, availability of product reviews, and easy comparison of prices), marketing has shifted from a supply-side model to a demand-based one, in which customers' perspectives are factored into the supplier-centric approach of the 4Ps. Products are now viewed as solutions for the customer, promotion now includes transfer of information, price has been replaced by consumer value, and placement is viewed as access.

To identify market segments that might purchase a product or service, and to determine what qualities that segment would find most valuable, marketing research utilizes complex analytical tools such as regression analysis, conjoint analysis, perceptual maps, and scenario planning to make decisions. Fig. 5.2 demonstrates the crowded landscape of facial rejuvenation, in which patients may choose from a number of interventions, based upon such parameters as price, durability, invasiveness, and time to recovery. Marketing seeks to identify which customers want what procedures and to target that group specifically. Occasionally, uncontested market

Fig. 5.2 Marketing: perceptual map of facial rejuvenation.

space is discovered, based upon changing customer preferences, or opens up, due to advances in technology.

The act of connecting customer to product or service is central to the charge of marketing and can reap tremendous returns, in terms of revenue, branding, and goodwill. As such, marketing is viewed as an investment by the company, similar to research and development, in which return on investment is predicted and carefully studied, along with other metrics such as market share, customer attrition, customer satisfaction, exchanges and returns, and size of accounts receivable. Other research tools include customer focus groups, demographic data, and customer questionnaires.

In addition to using such strategies as segmentation, targeting, and positioning, marketing also can utilize branding as a powerful tool to communicate the qualities of a new offering. In many ways, a strong brand serves, albeit not legally, as a promise that the new product or service will be similar to previous offerings. Branding can include a logo, phrase, image, or feeling that serves as a placeholder for the company and its reputation.

One strategy that is not particularly effective but must be mentioned, to warn against, is that of perceptual shifting. This occurs when: 1) promotion attempts to shift the needs and desires of a targeted group, so that they believe that they need or desire the product or service; or when 2) promotion shifts the perceived qualities of the offering, so that these features more closely correspond with the needs and desires of the targeted group. Such a strategy will produce a very short-term effect, which may temporarily improve sales, but will have disastrous long-term effects on the relationship with the customer. This strategy is employed when firms do not desire repeat transactions with their customer or when a product is reaching obsolescence and the entire industry is shrinking.

With the recent decline in print media and other traditional communication outlets such as radio and network TV, marketing has turned to the internet to promote goods and services, provide information to the consumer, and match the appropriate offering with the correct group. Many economists arguably contend that in our new digital age, the cost of storing information is approaching zero and the value of

BOX 5.5 Idea watch: marketing

Reference: Avery J, Fournier S, Wittenbraker J. Unlock the mysteries of your customer relationships. *Harvard Business Review*. 2014;92:72–81.⁶⁹

Many consumer companies, including service industries like healthcare, lack relational intelligence and do not appreciate the different kinds of relationships that their customers have with their brand, their product, and their service. Each type of customer relationship is based on that customer's experience, expectations, and future desires.

Customers can now be described as strangers, flings, acquaintances, buddies, teammates, best friends, and even enemies. As such, marketing divisions must crunch big data to determine the signal within the noise, in terms of providing the right customer with the right product or service within the context of the right experience. Meeting or exceeding consumers' needs must still occur, but marketing experts must consider the new rules, which include:

- Bolster desired relationships
- Renegotiate existing relationships
- Reorganize marketing strategy around relationships
- Create new roles for employees to develop relationships
- Expand the marketing umbrella within the organization create a culture of relationship-driven strategy

information may creep toward infinity.⁶³ Despite whether or not this can be proven, it is clear that digital information has completely changed the rules of marketing. Companies can gather specific information about consumers, based upon their shopping habits at Amazon, their friends on Facebook, what they write on blogs in the Huffington post, and what articles they read at CNN.com. For a fraction of the cost of traditional media, firms can reach out to their customers through direct email or via search engines. Marketing departments now focus on search engine optimization and search engine marketing. As some companies experiment with new revenue streams, both online and offline, some products may be offered for free, while related services may cost a premium.

Operations

"Any customer can have a car painted any color that he wants, so long as it is black."

Henry Ford

Operations can be defined as matching supply with demand (Box 5.6).^{18,19} Although economists can describe how prices change with alterations in supply and demand, managers responsible for production of inventory or for coordination of services have an entirely different perspective: excess demand is lost revenue, and excess supply is wasted resources. How the manager balances supply and demand determines not only potential revenue from goods and services but also operating costs, which together yield operating income for the firm.

Operational effectiveness is critical to the firm's success; in fact, this can be a source of competitive advantage. Companies that get more from their inputs, or use fewer inputs, to produce higher quality outputs will be able to offer goods or services

at lower costs than their competitors or extract more financial value from these goods and services. This flow of inputs to outputs is also called the supply chain, and when managed well, adds value to the final product, before this is passed on to the consumer.

To optimize the flow of this value chain, the field of operations utilizes elements of queueing theory to predict and control demand, as well as the theory of constraints, to predict and control supply. Perhaps the greatest challenge in determining demand for a good or service is variability. In medicine, for example, long clinic waits to see a physician are often due to variability in patient arrival times, which is compounded by a variability in service times by the provider. This is why patients of a certain type are often scheduled in batches, to minimize the variability on both sides of the equation. In the service industry, key metrics that should be tracked, in an effort to improve operational effectiveness, include:

Capacity = maximum supply a process can generate

Capacity utilization = arrival rate/service rate

Throughput time = wait time + service time

Flow time = (1/service rate)/(1 – capacity utilization)

Inventory = average flow rate ×
average flow time (Little's Law)

Inventory turns = 1/flow time = COGS/inventory

Bottlenecks in the production process (for goods) or delivery process (for services) occur when the demand at a specific station in the flow process is greater than the outputs produced at that station. At any given point, a process has technically only one bottleneck, which is defined as the resource with the lowest capacity. Flow through a station can be measured to identify the bottleneck, but this point of constraint is often evident by high utilization, no slack or buffer, piled-up inventory, and complaints from workers and consumers.

Principles used to match supply with demand include:

1. Since the limiting resource defines capacity, focus on improving output at the bottleneck (this, of course, creates a new bottleneck somewhere else in the system).
2. Maintain enough inventory and work-in-process to keep the pipeline flowing, to prevent stock-out, and to anticipate variability in demand, but not too much that capital is over-invested on unfinished goods or unused services.
3. Systems or stations operating at close to 100% capacity are not sustainable; 80% utilization is considered to be a reasonable target.
4. Plan carefully, as variability and uncertainty can propagate along the supply chain, creating a bull-whip effect of increasing impact that yields far too much or far too little output.
5. Prevention costs less than inspection and correction; never add value to a part that is defective.
6. Never allow the cause of the problem to persist by working around it.
7. High quality is not free, but it can be a great investment.

8. Forecasts are always wrong, sometimes more so than others.
9. Service industries face unique challenges that involve customization of the output and high degree of labor interaction.

In an effort to improve operational efficiency, a number of methods have been developed to reduce defects, increase throughput, and improve quality. Lean manufacturing is a production process in which any expenditure or resource that does not add value to the customer is a target for elimination. Originally developed by Toyota, lean manufacturing attempts to “work smarter, not harder” by reducing or eliminating seven sources of waste: overproduction, unnecessary transportation, inventory, motion, defects, over-processing, and waiting. Although this approach yields only incremental improvements in operations, the system itself was an innovation that provided competitive advantage over other firms in the automobile production industry.

Another methodology that provides incremental improvements, through reduction in defects and quality improvement, is Six Sigma, originally developed by Motorola. Using the DMAIC model of **Define, Measure, Analyze, Improve, and Control**, experts (known as Black Belts, Green Belts, and Yellow Belts, depending upon level of training and responsibility) attempt to improve the quality of process outputs by minimizing variability in the production line and reducing defects or errors to less than 3 per million (6 standard deviations from the desired target, thus 6-sigma). Quality management tools used to identify areas needing improvement include business process mapping, cost-benefit analysis, critical to quality trees, Pareto charts, and SIPOC analysis (suppliers, inputs, process, outputs, and customers). After determining the root cause of defects or inefficiencies, Six Sigma experts apply and test such interventions as contingency planning, parallel processing, and workflow redesign to reduce defects, improve quality, and maximize throughput. Although the methodology of Six Sigma provides only incremental improvement to inefficient systems and may, in fact, stifle “outside-of-the-box” innovation, improvements in operational productivity and quality may yield substantial financial rewards, in terms of cost savings, company goodwill and branding, and customer and employee satisfaction.

In service industries, the value chain can be strengthened by not only focusing on quality but also stakeholder happiness. In “Putting the service-profit chain to work”, Heskett *et al.* describe a model of stakeholder satisfaction, in which internal service quality yields employee retention and productivity, which in turn drives up external service value, securing customer loyalty and retention, which has direct impact on revenue growth and profitability.²⁰ Employees and consumers can move from a zone of indifference to zones of affection or defection, depending upon their level of satisfaction. In fact, Jones and Sasser argue, in “Why satisfied customers defect,” that complete customer satisfaction is the key to securing loyalty – intent to repurchase – and generate superior long-term financial performance.²¹ Different industries have different loyalty/satisfaction curves, creating a mixture of consumers that includes apostles, loyalists, mercenaries, defectors, hostages, and terrorists. Companies should direct efforts at achieving complete satisfaction to retain the loyalists and attract the mercenaries (the apostles will stay), while the

BOX 5.6 Idea watch: service operations

Reference: Porter ME, Lee TH. The strategy that will fix health care. *Harvard Business Review*. 2013;91:50–70.⁷⁰

Perhaps the industry with the most potential, and most need, to improve its performance is healthcare. The combination of rising costs, uneven quality, limited access, and disparate outcomes has led to a crisis in which the health of our economy, and our nation, is at stake. Michael Porter is calling for a fundamentally new strategy. Previous efforts, such as changing public policy, improving patient safety, implementing evidence-based guidelines, involving patients as consumers, reducing fraud, and implementing electronic health records, have yielded small, incremental changes, at best. Instead, value must become the overarching goal.

Transformation to a high-value healthcare delivery system must involve the simultaneous cooperation of administrators, providers, patients, health plans, and employers, to deploy the following strategic agenda:

- Organize into integrated practice units
- Measure outcomes and costs for every patient
- Develop bundled prices for care cycles
- Integrate care delivery systems
- Expand areas of excellence across geography
- Build and exploit an enabling information technology platform

terrorists should not be pursued and hostages should be let go. In healthcare, patients who are not completely satisfied or mostly satisfied will find other providers.

Innovation

“Companies that enjoy enduring success have core values and a core purpose that remain fixed, while their business strategies and practices endlessly adapt to a changing world.”

James Collins and Jerry Porras

Whereas the field of operations provides value through incremental improvement, innovation (Box 5.7) produces radical or revolutionary changes in thinking, design, products, processes, and even organizations.^{22–25} Operations serve to exploit existing inefficiencies, with the goal of lower costs, faster production, and higher quality, via such interventions as tighter supply chain coordination, lean manufacturing techniques, and zero-defect policies. Innovation, on the other hand, disrupts the current paradigm and not only expands the existing market but may create entirely new markets. Thomas Krummel, a pediatric surgeon who directs the Stanford Biodesign Program, describes a sequence of discovery, invention, innovation, and entrepreneurship that is the blueprint for translational medicine.²⁴ More importantly, he asks, “why should innovation be left to chance?” and provides a cogent argument for studying, understanding, and teaching innovation. Medical knowledge can be utilized directly in patient care, but training other physicians, developing new solutions, and applying new technologies can increase the impact of surgeons exponentially.

A reasonable question, which has a surprising answer, is “why do we need to innovate?” Peter Drucker, in fact, wrote that the two essential functions of a company are innovation

and marketing, because these create real value; all other processes are costs.²² Since the business environment is always changing, the position of a company, relative to its competition, new entrants, substitutes, suppliers, and consumers, is also in flux. A company that enjoys dominant market share today could become easily displaced tomorrow. Apart from innovation, the only competitive advantage that a company can maintain is based upon incremental improvements in price, quality, and access – until a new company introduces an innovation that dramatically affects these qualities, significantly expands the size of the market, or actually changes customer needs and preferences. Innovation is most effective and needed during periods of stability, whereas process improvement is most valuable to a company during periods of growth.

Successful innovation requires discipline and hard work, in addition to creativity. Companies that have mastered the process of innovation, such as Apple, Mayo Clinic, and the design firm Ideo, follow a roadmap that consists of four phases: breakthrough or discovery, platform development, derivative changes, and maintenance. Through a carefully orchestrated plan, in which these phases overlap, project managers allocate resources (time, money, people) based upon importance of each phase, level of uncertainty, and location in the critical pathway. Apple may introduce a new product, such as the iPod, iPhone, and iPad every few years, but each of these devices undergoes an iterative process of

improvement and value-added upgrades in technology. By having a diverse portfolio of new products, Apple is ensuring the success of its company, similar to a mutual fund with multiple investments. Occasionally, such innovation is disruptive, displacing some products, increasing competition with a company's own products, and creating new markets for other entrants. Such is the case with digital music; Apple changed from a computer company to an information and communications company, within a decade. Apple was able to apply breakthrough technology to create new products. If Apple had focused on incremental improvements in their operating system or software, as Microsoft has done, then such spinoff applications as e-books, online newspapers, and of course iTunes might not yet exist. The real challenge will come from Google, which started as a search engine but now intends to dominate the landscape of cloud computing.

Three drivers of successful innovation are understanding the consumer, “crossing the chasm”, and managing failure. To succeed over a long-term horizon, companies need to serve and retain their existing customers and acquire new ones by applying incremental and disruptive technologies. The focus of any commercial venture should start with the voice of the customer – listening to what the customer wants – and should finish with what the customer needs. Good marketing may be able to identify needs that do not yet exist, or segments of the population that have not been identified. Second, anticipate who will need the product or service, and when. Prototypes and early versions (think iPhone v1.0) are critical in attracting the innovators (our medical students) and early adopters (our residents), who will demonstrate product viability and create an early buzz. Return on investment, however, will not occur until the early majority (me) and late majority (my boss) adopts this technology. Even laggards, who usually resist new technology, may be an attractive group to target, as they may become the early adopters of the next technology. Crossing this chasm, from early adoption to market penetration, is where most companies fail. The third component of successful innovation, then, is learning from failure and managing failure. Just as lean manufacturing and Six Sigma permit

BOX 5.7 Idea watch: innovation

Reference: Christensen CM, Raynor M, McDonald R. One more time: what is disruptive innovation? *Harvard Business Review*. 2015;93:44–53.⁷¹

Two decades after introducing the theory of “disruptive innovation”, Clayton Christensen and colleagues set the record straight. While disruptive innovation has proven to be a powerful way to fuel innovation-driven growth, not all innovation is disruptive, and certainly not all disruption is innovative.

The authors remind us, “disruption describes a process whereby a smaller company with fewer resources is able to successfully challenge established incumbent businesses . . . which focus on improving their products and services for their most demanding (and usually most profitable) customers” – exceeding the needs of some segments and ignoring the needs of others. Uber, for example, is clearly transforming the taxi business, but its financial and strategic achievements do not qualify the company as disruptive. According to Christensen's theory:

- Disruptive innovations originate in low-end or new-market footholds
- Disruptive innovations don't catch on with mainstream customers until quality catches up with their standards.

Although Uber has increased total demand in the taxi sector – because the company developed a better, less expensive solution to a widespread customer need – Uber did not start in low-end or unserved markets. Instead, Uber created sustaining innovations that actually improve the taxi business, such as booking rides on a smartphone app, using GPS to reduce wait times, offering cashless payments, and providing passengers and drivers with the ability to rate each other. Furthermore, Uber uses a variable pricing algorithm that usually results in a less expensive ride, which is more punctual and reliable than traditional taxi services. An area where Uber may truly produce a disruptive innovation is the application of this technology to ride-sharing and car-pooling, as an alternative to our solo commutes to work.

Fig. 5.3 Innovation: incremental change in breast reconstruction.

Fig. 5.4 Innovation: disruptive change in breast reconstruction.

incremental improvement in production systems, controlled experimentation increases the yield of innovation efforts. Measures to minimize risk include separation of invention from execution, maintaining a diverse and deep pipeline of ideas and projects, and collaborating with people outside of your area of technical expertise or “comfort zone”.

In the field of plastic surgery, breast reconstruction has experienced both incremental and disruptive innovation, involving alloplastic materials that continue to be refined (silicone and saline implants), as well as surgical methods that utilize vascularized tissue (latissimus, transverse rectus abdominis myocutaneous (TRAM), and perforator flaps). The recent introduction of fat grafting, initially used to correct contour deformities, may actually supersede conventional methods of reconstruction, to become a primary method of breast replacement (Figs 5.3 & 5.4). In addition to such factors as durability and cost of reconstruction, the value chain will also need to incorporate patient and provider preferences, until a new market equilibrium is established.

to gain the support of investment bankers, suppliers, and customers.

Perhaps the most important resource to an entrepreneur, though, is an asymmetry of knowledge. Entrepreneurs may be aware of: 1) macro-economic forces yielding change in demographic, social, and cultural norms; 2) new technologies without defined applications; and 3) existing inefficiencies embedded within current industries. Such incongruities, in the setting of new technology and changing markets, represent tempting opportunities for entrepreneurs. Good entrepreneurs find opportunities; great entrepreneurs make opportunities. One example of capturing latent value in healthcare is to move ambulatory services out of the hospital, which carries a high overhead burden, and into ambulatory settings, where overhead costs are lower, and variable direct costs can be more accurately measured and controlled. An accredited, office-based surgery facility may actually improve quality and safety, in addition to decreasing the cost of care and improving patient satisfaction (Figs 5.5 & 5.6). Moving

Entrepreneurship

“The people who get on in this world are the people who get up and look for the circumstances they want, and, if they can’t find them, make them.”

George Bernard Shaw

Whereas technology is the way that you do things and innovation is the way you do new things, entrepreneurship (Box 5.8) is the way that you increase the value of what you do.²⁶ Entrepreneurship is a way of thinking, as well as a process, that increases the impact of innovation. An entrepreneur articulates a vision and develops a system that assembles inputs, creates a product, service, or information, and captures new value from the outputs. Entrepreneurial leaders act to bring a future business possibility into existence, with a sense of urgency, not constrained by limitations in capital, personnel, or productions. Instead, the entrepreneur utilizes his or her imagination, drive, passion, and networking,

Fig. 5.5 Entrepreneurship: location of services, volume, and revenue. ASC, ambulatory surgical center; ED, emergency department; OR, operating room.

Fig. 5.6 Entrepreneurship: effect of shifting location of care. ASC, ambulatory surgical center; ED, emergency department; OR, operating room.

the correct activities to the most appropriate location makes sense, creates value, and improves the patient-provider experience.

What is the process, then, for turning a challenge into an opportunity? The first and single most important act is to establish a value proposition, which can be defined as that core competency which makes your product or service unique and valuable. The value proposition presents a problem and solution, describes what you do and how you do it, and serves to differentiate you from the competition – all in one sentence. From this value proposition, the entrepreneur next develops a business model, which must then be translated into a business plan. The addition of a marketing plan, financial pro formas, and an operations template helps the entrepreneur create a true value-chain, mapping out the process path of the product or service (Fig. 5.7). These elements are linked by strategy, which describes how to achieve the value proposition, or specifically, how the product or service will reach the initial beachhead segment and possibly penetrate the general market (Fig. 5.8). Leadership serves as the cohesive force that manages, directs, and grows the entire enterprise. Leaders must fulfill the value proposition and ensure that the mission, vision, and values of the enterprise remain consistent and virtuous.

With details carefully thought out and available to potential stakeholders, the entrepreneur must seek support for this plan

Fig. 5.7 Entrepreneurship: aligning the elements of a new venture.

Fig. 5.8 Entrepreneurship: linking the elements of a new venture.

through different types of communication. The elevator pitch, which is a 30-second distillation of the new venture, is designed to attract interest and pique the listener's curiosity. The executive summary is a one-page summary of the business plan, whereas the business plan is a highly detailed document, ranging from 20 to 60 pages, designed to address specific questions, as investors look further into the venture. A ten-minute overview, typically delivered as a PowerPoint talk, is also necessary to get investors to actually read the business plan.

At every stage, the entrepreneur seeks to increase the interest of potential stakeholders and actively listens to feedback, so that the business plan can be revised, rewritten, and refocused, as often as needed. If the entrepreneur can gain the commitment of the stakeholders, then begins the process of raising capital, carefully managing cash, and coordinating logistics. Entrepreneurs typically bootstrap for as long as they can, utilizing human, intellectual, and social capital, rather than borrowing money or seeking outside funding. Entrepreneurs know that that worst time to raise money is when they absolutely need it, because they must cede control and ownership of the company, each time investors are brought on board with an influx of capital. Venture capital is particularly challenging to accept, because these investment bankers demand a 5–7× return on their investment, within a time horizon of several years, and because their exit strategy is ultimately about sale of the company, not necessarily growth of the company. Angel investors, friends and family, philanthropy and endowments, academic and community grants, small business loans, and even credit cards are more attractive (but limited) sources of capital, permitting the entrepreneur to retain control as long as possible. Finally, the cost of capital is highest at the beginning of the venture, because the risk is greatest, and borrowing costs decrease as the venture becomes more successful.

Writing a business plan is an art that entrepreneurs must master. Fig. 5.7 depicts a model that can be used when designing the elements of a new venture. Much like writing abstracts and journal articles, repetition improves the quality of the product. But unlike scientific papers, which are published

once and do not change, business plans are living documents that are constantly in flux and mandate frequent update. Nevertheless, a typical business plan follows an established model and contains the following components:

1. Executive summary
2. Value proposition
3. Vision, mission, values statement
4. Marketing analysis
 - a. Situation analysis
 - i. Environment
 - ii. Trends
 - iii. Company analysis
 - iv. Competition
 - v. Alliances
 - b. Target market and segmentation
 - c. Positioning and differentiation
 - d. Channels
 - e. Branding
 - f. Sales tools
 - g. Marketing budget
5. Business model
 - a. Description of service or product
 - b. Revenue streams
 - c. Variable costs
 - d. Overhead and fixed costs
6. Strategy
 - a. Beachhead segment
 - b. Value chain
 - c. Growth
 - d. Response to competitors, new entrants, substitutes
7. Governance and management teams
8. Financial pro formas (typically 3–5 years)
 - a. Income statement
 - b. Balance sheet
 - c. Cash flows: operations, financing, investments
 - d. Time to break-even
9. Debt and equity structures
10. Operations
 - a. Planning: Gantt chart
 - b. Implementation
 - c. Throughput assessment
 - d. Continuous improvement plans
11. Legal and regulatory issues
12. Sustainability practices (triple bottom line of people, planet, profit)
13. Barriers and roadblocks
14. Contingency plans
15. Exit strategy

Eventually, the CEO entrepreneur, having built a successful company, must make some major decisions, beyond resource allocation and management of revenue streams. In the short run, the leader will need to delegate operational decisions, while he or she focuses on setting strategy, team building, establishing culture, and reinforcing vision and values. Ultimately, however, the entrepreneur may recognize an internal calling to cede control, so that he or she can begin the process again, with a new idea, perhaps in a new industry, with a new

BOX 5.8 Idea watch: entrepreneurship

Reference: Isaacson W. The real leadership lessons of Steve Jobs. *Harvard Business Review*. 2012;90:92–102.⁷²

Walter Isaacson, former CEO of CNN and author of best-selling biographies on Benjamin Franklin and Albert Einstein, and Steve Jobs, identifies the practices every CEO can try to emulate. Isaacson writes of Jobs: “His saga is the entrepreneurial creation myth writ large.” By transforming seven industries (personal computing, animated films, music, phones, tablet computing, retail stores, and digital publishing), Steve Jobs will be remembered not for his personality, but how he applied imagination to technology and business. Jobs succeeded by pursuing the following practices:

- Focus
 - Simplify
 - Take responsibility end to end
 - When behind, leapfrog
 - Put products before profits
 - Don't be a slave to focus groups
 - Bend reality
 - Impute
 - Push for perfection
 - Tolerate only “A” players
 - Engage face-to-face
 - Know both the big picture and the details
 - Combine humanities with the sciences
 - Stay hungry, stay foolish
- I would add, “Think different.”

market. Others, however, remain with the company as a technical advisor or may serve on the Board of Directors, content with knowing that despite great odds, they created something of value. To paraphrase Steve Jobs, they “put a ding in the universe”.

Sustainable enterprise

“If you want to go fast, go alone. If you want to go far, bring others with you.”

African proverb

Sustainable enterprise (Box 5.9) is a well-established concept that has recently caught the attention of academics in organizational behavior, business executives, supply chain managers, shareholders, and even consumers.^{27–34} The importance of sustainable enterprise is so great that specific companies, as well as entire industries, are reassessing their vision and values, so that organizations can meet a new triple bottom line of “people, planet, and profit.” Green business, or sustainable enterprise, produces no or little negative impact on global or local environments, the community, society, or the economy, with specific attention to progressive human rights and environmental policies.

Previous efforts toward “reduce, reuse, recycle, repair, and redistribute” have been replaced by more aggressive attempts to minimize the carbon footprint of a business, search for renewable energy sources, and lessen the impact of waste materials on the environment, with the goal of establishing a

business that meets the needs of the present, without compromising the ability to meet the needs of the future. Specific examples of sustainable business practices include telecommuting, having a paperless office, minimizing shipping and packing material, leasing equipment that can be returned and refurbished, lean production methods which utilize less raw materials and produce less inventory, continuous improvement processes in the supply chain, and conducting business in LEED-certified buildings, which have lower energy requirements and are made of post-consumer materials. Products of service are durable goods that the manufacturer plans to re-process (thus the term “cradle-to-cradle” when describing the responsibility of the manufacturer), and products of consumption are short-lived materials that are non-toxic and biodegradable.

These sustainable business practices have coalesced into the more formal principle of corporate social responsibility, in which self-regulation is integrated into the overall business model of a company or industry. Businesses have discovered that sustainable practices can generate lasting value to shareholders and stakeholders, in terms of quality, access, and cost of services and goods. Such leaders as Ikea, Nike, Ford, and even Wal-Mart have been able to reduce expenses, minimize risk, increase revenues, and create stronger brands by building environmental and social thinking into their business strategies. Most large companies now have a Chief Sustainability Officer and publish an Annual Sustainability Report that corresponds to the Annual Financial Report.

What can we do in healthcare, and specifically plastic surgery, to leverage green practices and improve our triple bottom line? Interestingly, plastic surgery has been a leader in social justice for decades. Mission trips to developing nations, in which specialized services are provided and re-usable equipment is donated, has been a focus of many plastic surgeons, who could have spent more time in their private practices and generated more money for their businesses. What is especially admirable, in terms of sustainability, is the effort to teach these surgical techniques to providers in developing nations, so that infrastructure is developed and continuity of care is established, between visiting groups and the local communities. For surgeons who do not travel outside of the United States, multiple opportunities exist within our borders to establish similar exchanges, which can include work done at Native American reservations, in underserved areas like Appalachia, or at a community clinic. Even maintaining on-call emergency department privileges, performing lower-reimbursing reconstructive surgery, and assuming some indigent care all count as sustainable efforts, as the surgeon is contributing to a triple bottom line that does not neglect the needs of his or her local community. Such volunteerism is sustainable enterprise and should be a goal for all who practice this craft.

Healthcare, in general, has lagged behind other industries, in terms of sustainable business practices. One definition for sustainable medicine is the improvement of health within the natural life cycle, which seeks to avoid strain on social, environmental, and economic systems, so that new technologies can benefit all people within a community, not just those who can afford it. Extending this definition to the entire population of our planet, we have a moral obligation to provide basic healthcare to all, in the form of clean water, food, vaccinations, and preventive medicine. Jeffrey Sachs, a

BOX 5.9 Idea watch: sustainable enterprise

Reference: Porter ME, Kramer MR. Creating shared value. *Harvard Business Review*. 2011;89:62–67.⁷³

Having developed the concept of the value chain, as it relates to the creation of value along the supply chain, Michael Porter now proposes that value created should be shared with the society. Not only does this fulfill the social responsibility of the enterprise, but this may also be really good for business, with the power to unleash the next wave of global growth. Porter argues that societal needs, not just conventional economic needs, define markets, and social harms can create internal costs for firms.

Porter defines “shared value” as policies and operating practices that enhance the competitiveness of a company while simultaneously advancing the economic and social conditions in the communities in which it operates. Shared value creation focuses on identifying and expanding the connections between societal and economic progress. Shared value occurs by reconceiving products and markets and by redefining productivity in the value chain. For example, a company can address specific social concerns, such as water and energy use, employee health and worker safety, environmental impact, and supplier access and viability, as they relate to the specific products or services that the company produces. Whereas corporate social responsibility (CSR) is pursued separate from strategy and is determined by external pressures of sustainability, philanthropy, and citizenship, creating shared value (CSV) aligns social and economic needs to compete more effectively and to maximize profits. CSV is based on a company-specific agenda, internally generated, to realign the strategy of the entire enterprise.

Porter believes that CSV represents the evolution of capitalism, entirely consistent with Adam Smith’s “invisible hand.” Shared value benefits both the community and the enterprise. This self-interested behavior yields profits that create social benefits, rather than diminish them. Economic value is created by the commitment to generating social value.

progressive economist at Columbia University, and Muhammad Yunus, winner of the Nobel Peace Prize for his work on microfinance in India, both contend that we have both the resources and technology to end extreme poverty during our lifetimes. Part of the answer to eradicating extreme poverty is improving the health of those 2.5 billion people who exist at the “bottom of the pyramid” (individuals who live on less than \$2.50/day). Optimizing global health is possible with improved water purification systems, agricultural alliances to improve supply chain logistics, regulation of markets to eliminate corrupt middlemen in local markets, access to medical supplies such as antibiotics and antiretrovirals, and establishing microcredit and microloans. Once again, sustainable health endeavors are not only desirable from an ethical perspective, but such ventures can open new markets and new opportunities for investment.

Human resource management

“A small group of thoughtful people could change the world. Indeed, it is the only thing that ever has.”

Margaret Mead

Perhaps one of the most important, least appreciated, and often neglected components of business administration is human resources management (HRM) (Box 5.10), which can

be defined as that component of an organization that strategically manages the value chain of human capital.³⁵ Although employees cannot be considered an asset of a company, workers at all levels provide the critical steps of adding value to the product or service, as inputs are converted to outputs. Furthermore, employees, as well as customers, can be an incredible reservoir of innovation, if this resource is managed appropriately, in terms of recruiting, developing, retaining, and promoting talent. HRM is so critical to the success of an organization that HR practices often dictate the culture of that business and provide competitive advantage in and of itself, by attracting people of the highest quality and best fit. At Google, for example, employees are encouraged to spend 20% of their time on projects outside of their line of responsibility; such an environment fosters controlled experimentation and is directly responsible for that company's rapid ascent in the world of information technology.

Managing people is a daunting responsibility and when done correctly, looks effortless, but when not done well, creates a workplace that stifles creativity, undermines quality, and detracts from the value proposition of the company. As complex as managing human capital is, several best practices have emerged that can be shared:

1. Leadership starts with self-awareness.
2. Communication with employees is a central role of the manager.
3. Effective managers can articulate their own values and vision.
4. Effective managers foster an environment that brings out the best in others.
5. Effective managers are willing to engage in difficult conversations about difference.
6. Effective managers understand how groups work and focus on creating a culture of performance, with defined metrics, that enhances teamwork and collaboration.
7. Effective managers are change leaders.
8. Effective managers learn, reflect, and renew.

In healthcare, HRM often focuses on "workforce development", which refers to the continuing education and training of employees for current, new, and changing jobs. What a nurse does today may be very different from what he or she will do in the future, and employees must be able to adapt to the changing models of healthcare delivery. Not only must healthcare providers deal with changing technology and evolving systems of healthcare, but also these employees must be able to work well with people of different educational backgrounds, different generations (traditionalists, baby boomers, gen Xers, and millennials), and different work/life balances. Diversity in the workplace no longer refers to people of different cultures, but recognizes different values, work styles, and needs.

What HRM leaders have discovered in healthcare is that investing in the organization's people has a far greater ROI than trying to recruit superstar candidates for specific jobs. Furthermore, treating employees like customers, as well as customers as employees, is the key to both retaining providers and patients. Provider and patient satisfaction is very important, not only in the rankings of healthcare systems, but also in future revenue streams. Very satisfied patients will continue to seek healthcare with their same providers and will refer

BOX 5.10 Idea watch: human resource management

Reference: Fernandez-Araoz C. 21st century talent spotting: why potential now trumps brains, experience, and "competencies." *Harvard Business Review*. 2014;92:46–56.⁷⁴

The value of developing human capital, to increase the competitive advantage of an organization, cannot be overstated. Recognizing, recruiting, growing, and retaining talent remains critical for the growth of an enterprise and the ability to fulfill its mission.

Given the volatility, complexity, and uncertainty that characterize the current markets, however, employees who are merely smart, experienced, and competent may not add as much value to a company as those who have the ability to continuously adapt to changing business environments. Managers seeking new talent to develop should focus on potential, not necessarily past performance, based on the following indicators:

- The right motivation
- Curiosity
- Insight
- Engagement
- Determination

their friends and family. Such marketing is priceless. This practice of stakeholder fulfillment is not only good business, but also great medicine.

Legal and regulatory considerations

"To live outside the law, you must be honest."

Bob Dylan

As might be expected, the legal and regulatory components of healthcare are so labyrinthine that these considerations could easily occupy the contents of an encyclopedia (Box 5.11). Nevertheless, the plastic surgeon must be aware of the broad categories that affect his or her practice and, most importantly, have a low threshold to seek legal counsel, when needed. In addition to knowing about malpractice law, healthcare providers must have some familiarity with contract law, labor relations, corporate structure and liability, rules of emergency medical treatment, scope of practice by non-physician providers, certificate of need for and accreditation of outpatient facilities, and protection of patient confidentiality. A comprehension of these issues is not only recommended but is necessary, as providers must comply with state and federal regulations or face investigation, legal expenses, fines, court time, or prison, depending upon the degree of culpability, intent, and involvement.

The purpose of this section, however, is to examine how regulatory and legal changes in the business world have recently impacted healthcare as a business.^{36–38} Understanding the macroeconomics of and market changes in healthcare, as a result of government intervention, will hopefully assist the healthcare provider in making more informed decisions when delivering healthcare. This section will not debate the benefits or detrimental effects of regulation, but will rather present the changes that have occurred, as objectively as possible.

Before discussing how recent regulation has affected the business of healthcare, it is important to review the basic forms of business ownership. A sole proprietorship is an

entity owned by one person, who assumes personal liability for debts incurred by the business. A partnership is a type of business in which two or more individuals agree to share profits but also liabilities; the advantage of such a structure, like that of a proprietorship, is that net income is taxed only once. A corporation is a business with a distinct and separate identity from its members; for-profit and not-for-profit corporations must be owned by multiple shareholders and are overseen by a board of directors, which manages the executive team. Most hospitals follow this model, while many physicians in private practice may function as a proprietor or as the head of an S-corporation. Finally, a cooperative is a type of corporation with limited liability whose members, in contrast to shareholders, share decision-making capabilities. One disadvantage of corporations and cooperatives is that profit is subject to double taxation: first on net income of the entity, after operating and indirect expenses are deducted, and second on the returns to the stakeholders, in the form of personal income, dividends, and other capital gains such as stock that is sold.

Sarbanes–Oxley Act, 2002

In response to such corporate and accounting scandals as Enron, Tyco, and WorldCom, as well as the “dotcom” bubble that burst and cost investors billions of dollars, both the House and the Senate overwhelmingly supported and passed the Sarbanes–Oxley Act (SOX).³⁹ Public confidence in the nation’s securities markets had been greatly undermined, and this legislation attempted to restore the stability of these markets, through oversight and control. In addition to creating a Public Company Accounting Oversight Board, SOX mandated that: 1) auditors could not provide consulting services to the same clients; 2) senior executives must take individual responsibility for the accuracy and completeness of their corporate financial reports; and 3) financial disclosures of public companies must include enhanced reporting of off-balance sheet transactions, assumptions for pro formas, and stock transactions of corporate officers. Although SOX did not have provisions directly dealing with healthcare, this act affected the healthcare industry, as every publicly held company involved with healthcare would have to undergo significant restructuring of their accounting practices. Proponents contend that such legislation was essential to strengthen accounting controls and restore investor confidence, while opponents cite the overly complex oversight necessary for compliance, leading to reduced competitiveness with foreign businesses.

American Recovery and Reinvestment Act, 2009

As the United States headed into the worst recession since the Great Depression, Congress passed the American Recovery and Reinvestment Act, in an attempt to create jobs, promote investment, and induce consumer spending.⁴⁰ Because the Federal Reserve had already decreased interest rates to zero, with little effect on the credit markets, fiscal policy was chosen over monetary policy as a plan to stimulate the economy, and therefore an infusion of government capital – \$787 billion – was utilized to bridge the output gap created by a fall in consumer spending. Although the majority of the capital was

used to fund projects and programs in energy, communications, education, and transportation, healthcare received \$151 billion, with the vast majority of this money used to support Medicare. In the wake of this stimulus package, the national economy has remained volatile but appears to have stabilized, and the demand for healthcare services has not decreased, as many economists predicted.

Patient Protection and Affordable Care Act, 2010

In a bitterly fought, highly publicized partisan struggle,⁴¹ Congress eventually passed the Patient Protection and Affordable Care Act (ACA), which is essentially a healthcare reform bill that focuses on health insurance reform.⁴¹ Described as the most significant overhaul of the US healthcare system since Medicare and Medicaid in 1965, the ACA was enacted to increase the quality and affordability of health insurance, lower the uninsured rate by expanding public and private insurance coverage, and reduce the costs of healthcare for individuals and the government. Benefits of this legislation include expanded Medicaid eligibility, subsidized insurance premiums, incentives for small businesses to provide healthcare coverage, prohibition of denials by insurance companies, establishing a market of health insurance “exchanges”, and financial support of medical research and information technology, such as the electronic medical record.

Critics insist that the proposed deficit reduction of \$143 billion, over the first decade, will be neither achievable nor maintainable. The cost of this plan is offset by fees on pharmaceutical companies and on medical devices, new taxes on high-income brackets, improved efficiencies from information technology, and reduced administrative expenses. The Supreme Court has upheld the constitutionality of the ACA on two occasions, affirming the legality of the individual mandate and the federal subsidy, but ruled that individual states cannot be forced to participate in Medicaid expansion. However, over a third of the 32 million uninsured adults from 2011 now have health insurance, dropping the uninsured rate from 18.4% to 11.4%, by mid-2015.

Dodd–Frank Wall Street Reform and Consumer Protection Act, 2010

Already considered the most sweeping change to financial reform since the Great Depression, the Dodd–Frank Wall Street Reform and Consumer Protection Act is designed to permanently fix the economic problems that the Stimulus Act helped to stabilize.⁴² The aim of the bill is as follows: “To promote the financial stability of the United States by improving accountability and transparency in the financial system, to end “too big to fail”, to protect the American taxpayer by ending bailouts, (and) to protect consumers from abusive financial services practices.” The impact on the financial regulatory system will certainly be far-reaching, with significant restructuring of the flow of capital within our economy. Specific targets of reform include hedge funds and other investment banking instruments, the Federal Reserve, Wall Street transparency and accountability, mortgage and commercial lending institutions, and consumer and investor protection programs. The question for the healthcare industry is not if the Dodd–Frank Act will affect healthcare delivery, but how.

BOX 5.11 Idea watch: legal and regulatory considerations

Reference: Thacker PD. Consumers deserve to know who's funding health research. *Harvard Business Review* online, December 2, 2014; <https://hbr.org/2014/12/consumers-deserve-to-know-whos-funding-health-research#75>

Serving as the lead investigator for Senator Charles Grassley, who co-authored the Physician Payments Sunshine Act of 2010 (an amendment to the ACA), Paul Thacker helped to expose previously undisclosed payments made by drug and device manufacturers to doctors and teaching hospitals, over the course of several decades. While much of this funding could be considered legitimate, to support research and education, much of the funding was not, covering such activities as the ghost writing of scientific publications, public speaking events in which content was biased, and kickbacks for using specific drugs and devices.

Perhaps the most important ramification of this legislation, which requires that industry report all financial transactions with physicians, is the improved transparency of this relationship, such that real and potential conflicts of interest can be identified. Optics matter. In exchange for our right to self-regulate as professionals, physicians must apply our specialized knowledge and skill to the greater societal good, conforming to a body of ethics that is built on honesty and integrity.

Thacker's hope is that given medicine's leadership position in disclosing industry funding, it is time for physicians to lead their other colleagues in science to ensure that all scientific work remains transparent and independent. While the Sunshine Act remains controversial, and long-term effects are not known, there has been a shift toward transparency at the intersection of industry and medicine. We now recognize that all physicians face conflicts of interest, which should be managed proactively, if possible.

Negotiation

"You can't always get what you want, but if you try sometime, you just might find, you get what you need."

Mick Jagger and Keith Richards

Negotiation (Box 5.12) can be defined as "a dialogue intended to resolve disputes, to produce an agreement upon courses of action, to bargain for individual or collective advantage, or to craft outcomes to satisfy various interests".⁴³ Whenever a decision is made, negotiation occurs. If a surgeon decides to start a laser practice, he or she must examine the opportunity cost in pursuing that service and negotiate, with the stakeholders of his or her practice – receptionists, nursing staff, patients – how this change will impact the practice. If a junior partner wants to develop a microsurgical breast reconstruction practice, he or she must negotiate with the hospital for more operative block time, carve out with insurance companies a more favorable reimbursement schedule, and gain the blessing of the senior partners, who will have to cover these patients when the primary surgeon is not available and absorb these low margin cases into their revenue stream. If an academic plastic surgery practice wishes to develop and build an outpatient aesthetic center with procedural rooms, the division chief must perform a complex negotiation with multiple parties (the Dean, Chairs, hospital administrators), over multiple iterations, regarding multiple issues.

Although some individuals are blessed with excellent empathic and communication skills and can negotiate successfully, negotiation is a discipline that can be learned.

Practice and preparation are the keys to success. The field of negotiation, as an academic discipline, is a rich body of work that incorporates game theory, auction strategies, psychology, and behavioral economics. Perhaps the seminal work in this field is *Getting to Yes: Negotiating Agreement Without Giving In* by Fisher, Ury, and Patton.⁴⁴ The two overriding principles are: 1) knowing what you want versus what you need and 2) knowing what your opponent wants and needs. Negotiating begins with considerable preparation, not just predicting what your opponent will do, as if in a chess match, but what your opponent requires to improve his or her position. In fact, both opponents in a two-party negotiation may not even know what their best position is or why a certain solution may be favorable for each other. Creativity and communication are critical for success.

Negotiation, then, begins by developing and articulating your BATNA: the best alternative to a negotiated agreement. This is the walk-away position if no agreement can be reached, or "the lowest you will go", which should be ascertained before the negotiation begins. After deciding that you will not bargain over these positions, utilize the following four principles: 1) separate the people from the problem; 2) focus on interests and not positions; 3) invent options for mutual gain; 4) insist on using objective criteria.^{45–49}

These concepts of "principled" negotiation work most of the time. Occasionally, however, negotiation reaches an impasse, and breakthrough can be achieved by reframing the problem. Specifically, avoid escalation by not reacting, arguing, rejecting, or pushing. Step out of the situation, help the other side view the problem objectively, and reframe the problem from their perspective. Determine what options will provide mutual gain, or at the very least, minimize losses. In other words, pick your battles wisely. Concession is not failure, but often resets the parameters of the problem, so that future iterations of the "game" may yield an outcome in your favor.

Particularly difficult negotiations involve those individuals or groups who will not compromise over their demands, who have an asymmetry of information, who are unwilling to view the problem from your perspective, or who threaten to use power to enforce their solution. People who fall into this category are the schoolyard bully, an impaired physician, sociopaths, terrorists, and sometimes the "difficult patient", who may have an underlying body dysmorphic disorder. One

BOX 5.12 Idea watch: negotiation

Reference: Mikes A, Hall M, Millo Y. How experts gain influence. *Harvard Business Review*. 2013;91:70–74.⁷⁶

Is it better to be loved or feared? Effective negotiation can be accomplished by following a set of rules and guidelines, but how does one achieve influence on the decision-making of others? Projecting strength and warmth surely helps in the art of persuasion, but the authors of this paper identified four competencies that allow individuals to gain personal and organizational-wide influence:

- Trailblazing: finding new opportunities to use expertise
- Toolmaking: developing and deploying tools that embody and spread expertise
- Teamwork: using personal interaction to take in others' expertise and convince people of the relevance of your own
- Translation: personally helping decision-makers understand complex content

option is to not negotiate – step away from the situation – and use other means to resolve a dispute, such as legal action. However, skilled negotiators can still deal with these challenging situations effectively, by using uncertainty, chaos, and ambiguity to disarm opponents and neutralize their position. Successful negotiators can translate little gains into positive momentum, by focusing on future rounds of the negotiation and setting up more effective positions for the future.

Ethics

“Always do right, this will gratify some people and astonish the rest.”

Mark Twain

In healthcare, we are faced with multiple challenges that test our ethical grounding (Box 5.13). Healthcare providers must make numerous decisions regarding patient care every day, and society rightfully expects these providers to behave ethically. Competency in patient care and medical knowledge is required but not sufficient; providers must also demonstrate competency in interpersonal and communication skills, systems-based practice, practice-based learning, and professionalism, all of which involve a firm commitment toward ethical practice. So important are these competencies that medical education, residency training programs, state licensure, board certification and maintenance of certification, and hospital credentialing incorporate these elements in evaluating healthcare providers.

John Canady, past president of the American Society of Plastic Surgeons and former chair of its Ethics Committee, observed, “Plastic surgeons who are aware of competing interests that influence their decision-making processes stand a greater chance of achieving ethical outcomes. Nevertheless, with the growing volume of non-reimbursed care and expectations of perfect outcomes, achieving uniformly ethical decisions without burdensome self-sacrifice is difficult at best”.⁵⁰ Competing factors that influence decision-making for plastic surgeons include personal finances (ownership of surgery centers, selection of procedures, pricing), regulatory forces (Emergency Medical Treatment and Active Labor Act (EMTALA), Joint Commission on Accreditation of Healthcare Organizations (JCAHO), American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF)/Accreditation Association for Ambulatory Healthcare (AAAHC), Occupational Safety and Health Administration (OSHA), and Health Insurance Portability and Accountability Act (HIPAA) – to name just a few, and professional duty (informed consent, discussion of error).

When faced with a dilemma, healthcare providers must incorporate intuition and reasoning into making a decision. Resolution of an ethical question often requires careful consideration of culture, infrastructure, leadership/governance, and personal integrity. Ethical intelligence can be developed. In his book *Strengthening Ethical Wisdom*, Jack Gilbert argues that intentions, manifest by vision, mission, values, strategy, and goals, directly impact performance.⁵¹ In healthcare, this translates into patient safety, quality of care, productivity and throughput, patient and employee satisfaction, reputation, and financial health. Medical ethics is practical, case-based, and relative to the context of the situation.

Just as ethics helps to guide decision-making in healthcare, so too should ethics play a major role in the choices made by business entities. The history of ethics and capitalism is quite fascinating. Adam Smith, who published *The Wealth of Nations* in 1776, argued that markets were guided by “the invisible hand” to produce the right amount of goods for society, but that such a force was intimately tied to our ethical obligations to each other.⁵² Andrew Carnegie and other industrialists from the 1800s articulated the need for business to pursue charity and stewardship, both forms of social philanthropy, because with power comes responsibility. Even Milton Friedman, the Nobel-winning economist from the University of Chicago, who believed that the only ethical obligation of business is to maximize profits, emphasized that business efficiently creates

BOX 5.13 Idea watch: ethics

Reference: Anderson M, Escher P. *The MBA Oath: Setting a Higher Standard for Business Leaders*. New York: Portfolio Hardcover, the Penguin Group; 2010. <http://mbaoath.org>.⁷⁷

In response to several highly publicized business scandals of the early 2000s, academic leaders in business management have come forward to develop the MBA Oath.⁵³ The integrity of business, as a “profession”, was seriously compromised, involving fraudulent accounting (Enron), Ponzi schemes (Bernie Madoff), excessive executive compensation (widening of the salary gap between leadership and labor), business–government collusion (the revolving door between academia, Wall Street, and the Federal Reserve), and illegal derivative trading (one of the many causes of the Great Recession of 2008–2009). Similar to the Hippocratic Oath for physicians, this pledge acknowledges that management is a profession bound by ethical principles.

The MBA Oath

As a business leader I recognize my role in society.

- My purpose is to lead people and manage resources to create value that no single individual can create alone.
- My decisions affect the well-being of individuals inside and outside my enterprise, today and tomorrow.

Therefore, I promise that:

- I will manage my enterprise with loyalty and care, and will not advance my personal interests at the expense of my enterprise or society.
- I will understand and uphold, in letter and spirit, the laws and contracts governing my conduct and that of my enterprise.
- I will refrain from corruption, unfair competition, or business practices harmful to society.
- I will protect the human rights and dignity of all people affected by my enterprise, and I will oppose discrimination and exploitation.
- I will protect the right of future generations to advance their standard of living and enjoy a healthy planet.
- I will report the performance and risks of my enterprise accurately and honestly.
- I will invest in developing myself and others, helping the management profession continue to advance and create sustainable and inclusive prosperity.

In exercising my professional duties according to these principles, I recognize that my behavior must set an example of integrity, eliciting trust and esteem from those I serve. I will remain accountable to my peers and to society for my actions and for upholding these standards.

This oath I make freely, and upon my honor.

and allocates wealth in society if the stakeholders are honest, transparent, and just.

Today, business ethics is just good business. A new paradigm for delivering stakeholder value has replaced the previous model of maximizing shareholder returns. Because suppliers, customers, employees, competitors, and communities are all affected by the decisions of a business, a stakeholder-approach to organizational structure maps out these relationships and attempts to align competing interests, to maximize value creation of the networks, products, services, and information. Most business leaders are aware that values, rights, duties, and responsibilities must inform decision-making, much like these principles affect medical ethics. Consequences may not only have legal ramifications but may also impact the bottom line. Values-based capitalism strives to maximize stakeholder wealth by trying to humanize the institution of business and encourage stakeholders to perform at their best, not their worst. Key principles of values-based capitalism include: stakeholder cooperation, shared responsibility, recognition of complexity, continuous creation, and emergent competition.

Leadership

"The greatest accomplishment is not in never failing, but in rising again after you fall."

Vince Lombardi

The most concise answer to the question "what defines a leader?" is "someone who has followers." The real question, though, should be framed as follows: "what defines a great leader?" This answer is quite elusive, depending upon the leader, the context, and the constituents (Box 5.14).⁵⁴

In business, leaders must first and foremost be effective managers (Fig. 5.9). "The manager is the dynamic, life-giving element in every business. Without leadership, the 'resources of production' remain resources and never become production. In a competitive economy, above all, the quality and performance of its managers determine the success of the business, indeed they determine its survival. For the quality and performance of its managers is the only effective advantage an enterprise in a competitive environment can have." So begins *The Practice of Management*, published in 1954 by

Peter Drucker, considered to be an early, defining modern work on management theory and practice.^{55,56}

Although managers differ from leaders along many parameters, the skill sets of both are complementary and, when combined, provide synergy that enhances the strength of an organization:⁵⁷⁻⁶²

Managers administer	Leaders innovate
Managers ask how and when	Leaders ask what and why
Managers imitate	Leaders originate
Managers focus on systems	Leaders focus on people
Managers maintain	Leaders develop
Managers rely on control	Leaders rely on trust
Managers accept the status quo	Leaders challenge the status quo
Managers look at the bottom line	Leaders look toward and past the horizon
Managers do things right	Leaders do the right thing
Managers operate	Leaders strategize
But, managers often lead	Leaders often manage

Drucker continues, "To succeed in this new world, we will have to learn, first, who we are... Success in the knowledge economy comes to those who know themselves – their strengths, their values, and how they best perform". Individuals must determine where they belong and what they should contribute. In this age of discontinuity, where information has become as valuable as capital, and communication is critical to the flow of adding value, individuals must manage their own careers, carving out discrete niches, keeping themselves engaged, and knowing when to change course.

For leadership to be effective, the individual uses social influence to gain the support of followers, through positional, personal, and relational power, to accomplish a common goal. Many theories have been proposed to describe exactly how leadership works, but ultimately leaders must be responsible for a number of functions, such as delegation, empowerment, negotiation, conflict resolution, innovation, inspiration, and guiding change. Through a variety of leadership styles – forcing, avoiding, compromising, accommodating, and collaborating – leaders must also learn how to "manage from the middle". Serving as a conduit for transfer of information, knowledge workers today must manage up and down, both their supervisors and their direct reports. Those who can effect change in such an environment are incredibly influential, adding value to the human capital of an organization.

Perhaps the most critical function of a leader is the building of high-functioning, high-performing teams. Teamwork has become increasingly important in business, because of several factors: environmental complexity and pace, the dependence upon internal and external partners, the need for multiple sources of information, and the desire to have varied perspectives and diverse thought. The smartest of us is not as smart as all of us. Teams, however, do not automatically form and function smoothly. An effective leader builds collaborative teams that deliver results by establishing the following characteristics: goal compatibility, trust and commitment, interdependence and accountability, open communication and acceptance of ideas, and converting conflict into creativity. The leader also serves as the team's advocate, gaining support from senior executives, providing the necessary resources to

Fig. 5.9 Leadership: leading the new venture.

solve the problem, and keeping stakeholders informed. It turns out that being an effective team leader has less to do with technical knowledge and more to do with emotional intelligence and communication skills.⁶¹

Kouzes and Posner offer a simple but extremely helpful model of leadership in which credibility serves as the foundation for all future success. Having studied hundreds of leaders across many types of disciplines, they provide these recommendations for becoming a great leader: 1) model the way – clarify values and set the example; 2) inspire a shared vision – envision the future and enlist others; 3) challenge the process – search for opportunities, experiment, and take risks; 4) enable others to act – foster collaboration and strengthen others; and 5) encourage the heart – recognize contributions and celebrate the values and victories.⁶⁰ This model dispels the myth that “it is lonely at the top”, because the goal of leadership should be to bring everyone to the top.

Leadership at the very top – CEOs of large, complex organizations – no doubt requires social influence to achieve goals, but this type of leadership also contains unique challenges that require unique skills, to deliver effective direction and strategy, organizational structure, selection of people, and appropriate incentives. Porter and Nohria examined 110 newly appointed CEOs from mostly public companies, with median revenue of \$3.7 billion.⁵⁴ Average age at appointment was 49.7 years, and average time with the company had been 14.1 years. Seventy-five percent of these CEOs had been inside candidates, and 64% had a graduate-level degree.

The findings were surprising. Challenges specific to their new role as CEO included broader scope than anticipated, placating the Board of Directors, constraints in power, difficulty obtaining reliable information, maintaining visibility, having to produce within a limited time horizon, and expectations of change by the stakeholders. These CEOs discovered, however, that indirect levers could be quite powerful, by shaping context so that members of the organization could make good decisions, take appropriate action, and advance the mission of the company. Other interesting findings included:

Time spent working on issues internal to the company:	69%
Time allocated to core agenda items:	52%
Time spent in face-to-face communication:	81%
Time spent with constituents other than direct reports:	42%
Time spent communicating with groups:	63%

Based upon these observations, specifically that indirect levers of influence may be more important than direct levers, Porter and Nohria recommend that CEOs pay special attention to allocating their most limited, yet crucial resource: their presence. CEOs – and perhaps all leaders – can manage their presence by setting a clear personal agenda, communicating relentlessly, gathering information continuously, leveraging symbolism, and harnessing the power of a strong management team. Establishing legitimacy, through competence, fairness, results, and integrity, instills confidence in the stakeholders, who are then empowered to do their best.

BOX 5.14 Idea watch: leadership

Reference: Goleman D. The focused leader: how effective executives direct their own – and their organizations’ – attention. *Harvard Business Review*. 2013;91:50–60.⁷⁸

Dan Goleman introduced the idea that effective leaders must have emotional intelligence, but he now adds the skill of focus to the list of qualities that distinguish the best leaders. He points out that a primary task of leadership is to direct attention, and as such, the leader must first learn to focus his or her own attention. Furthermore, the concept of focusing is not just filtering out distractions, but rather concentrating on different topics, in different ways, for different purposes. Goleman cites recent neuroscience research that shows that focus is a complex cognitive function that draws upon the integration of multiple neural pathways.

To be effective and sharpen one's focus, every leader must cultivate an awareness of self and others. Both inward and outward focus are necessary to develop one's emotional intelligence. Self-awareness and self-control increase one's ability to focus on others. Social relationships are dependent upon directing attention toward others, and empathy emerges as the critical trait that is the hallmark of a natural leader, regardless of organizational or social rank. Goleman notes that the most effective leaders actually exhibit three types of empathy:

1. Cognitive empathy – the ability to understand another person's perspective
2. Emotional empathy – the ability to feel what someone else feels
3. Empathic concern – the ability to sense what another person needs from you.

The ultimate challenge of any leader is to take their organization from “good to great”. Jim Collins identified 11 publicly traded, stable companies that experienced substantial, sustained growth, as defined by financial performance several multiples better than the competitors in their industry.⁵⁸ Collins identified specific factors responsible for helping transition from “good to great”: focusing on core competencies, forging a culture of discipline, finding the right people to figure out where to go, confronting the brutal facts while maintaining hope, using technology accelerators, and creating momentum from the additive effect of small initiatives. What all of these companies had in common, though, was Level 5 leadership: CEOs who had personal humility and professional will. The most effective leaders were not outspoken and charismatic, but rather humble, selfless individuals who displayed fierce resolve in delivering the company's value proposition. Integrity and vision matter; these qualities confer upon the leader the ability to transform an organization from good to great.

Medico-legal issues in plastic surgery

Neal R. Reisman

SYNOPSIS

- Plastic surgeons will have a significant interaction with attorneys as they care for the injured, abused, and possibly negligently treated.
- Informed consent is a process, not merely a signed document.
- An express warranty may be established by including in the record a photo the patient believes will be the result.
- Fraud and abuse claims have NO statute of limitations and are not covered by liability insurance.
- HIPAA is created to protect patient privacy and covers medical records and photography.
- Agency Law places responsibility on the employer for employee negligence when performing work-related duties.
- Divulging patient information in a blog or social media website is an HIPAA violation.
- It is critical to notify your liability carrier as soon as possible if you receive notice of a lawsuit against you.
- Physicians who basically share an office may each be exposed to liability in caring for patients.
- Patient selection, when proper and appropriate, is the best method to avoid a negligence claim against you.

Introduction

Plastic surgeons have many interactions with the legal system. While medicine has many nuances and inferences, the law is steeped in legal doctrine, and the written word. An impression causing considerable concern is that if something is not recorded and written, it never occurred. The practice of medicine is filled with usual actions that may not be specifically documented, leading to a major conflict between medicine and the law. This chapter will focus on the interactions between plastic surgeons and the legal system and also methods of reducing medico-legal risk and improving patient

safety. Areas of the law will be presented and its impact on plastic surgical practice will be emphasized.

Interactions with attorneys and the legal system

Plastic surgeons can have a significant interaction with the legal system through their care of patients, which through injury and disease, may lead to legal representation. Work-related injuries, auto-accidents, animal bites, and domestic abuse often will initiate a lawsuit. The physician will participate in documenting injury, future medical expenses, and commenting on disability and scarring usually through a deposition and occasionally live testimony at trial. There are those who abhor any interaction with attorneys, but realistically many feel it appropriate to participate in the legal system and certainly represent and assist their patient. There are some guidelines and rules to follow. The Health Insurance Portability and Accountability Act (HIPAA) now requires written consent before you can discuss any patient information with anyone outside of the medical treatment area. An attorney acting within ethical guidelines will provide you with an authorization by their client and your patient to discuss the patient's care and treatment. You are prohibited from discussing the patient's information without such authorization. Do not be fooled by legal-appearing or court-initiated papers that seem to override written approval. Ask the attorney for authorization and confirm with your patient as necessary. If a deposition is required, assure that you have proper written authorization.

It has also been suggested if you are hired as an expert, that you seek advanced payment for your time and establish a written agreement that if the deposition is canceled more than 2 weeks from the scheduled date, you will refund the payment. If the deposition is canceled in the second week, then one half of the payment will be refunded, and if it is canceled closer

to the scheduled time, the payment will be forfeited. Establish an hourly rate and seek 2 hours in advance. It is also wise to schedule a deposition at the end of the day and not in the middle, which could significantly interfere with patient scheduling.

Legal interactions: depositions and narratives

Much of the correspondence between the plastic surgery practice and an attorney may be in their request for an official narrative outlining care, past treatments, future concerns, and specific questions the attorney might pose. The medical narrative should be factual and list what sources are used and what the report is based on. One should be honest in describing past and future concerns and not be too overreaching or inadequate in description. It is common to cite that your opinions are based on a review of certain documents, discussions with the patient, and the conclusions are based on training and experience. Depending on state law, there is usually a customary fee for such a narrative, which should be collected in advance of any dictation to the record. It is important to cite when references are used, for it is not uncommon to be given certain documents to help influence your opinion. When all these documents are subsequently reviewed, opinions may differ from the original narrative, which can now be explained by specific lists of information reviewed.

Areas of the law

There are many areas of the law that have an impact on plastic surgical practice. Most will include a claim of negligence, which initiates your malpractice insurance. Other claims either strengthen the malpractice claim or add additional claims that are not covered by your malpractice insurance; all are intended to add additional pressure to settling the suit.

Tort law: negligence, malpractice

Tort law is the basic area of the law covering negligence and malpractice. There are four requirements of the negligence action. The first area is a duty to provide care and acts in question. The second is that duty is breached, usually in a sub-standard way. The third requirement is that the breach is directly responsible for whatever damages occur. This is called proximate cause. And the fourth requirement is that there are damages as the result of the prior three requirements. The proof and arguments surrounding these four elements comprise a malpractice claim. Other legal interactions will also involve your testimony establishing these four elements. An example would be a dog bite resulting in a lawsuit. You have surgically repaired the laceration and now must testify that this injury is from the dog and the damages that you describe are directly the result of the bite. While this may appear ridiculous, as these questions are posed to you, you can now see that the three elements of this tort case can be established. The first element of that duty might be to protect people from the dog.

Informed consent

The doctrine of informed consent is a necessary part of both legal interactions and patient care. There are two standards

utilized for informed consent. A few states utilize the reasonable “doctor standard”, which states that information a reasonable physician thinks is important must be presented to a patient for their informed consent. More commonly, a reasonable “patient standard” is used. The standard states that all information a reasonable patient would want and need to know should be presented as they make their informed choice. There is much confusion about how much information should be outlined and in what fashion. There are those who believe the informed consent process should be videotaped as there is always a question after-the-fact about what was discussed or presented. This is usually unnecessary as documentation should include the process of information presented, questions asked and answered, and finally an understanding of what the physician can and cannot do. There are many styles of learning and current thinking is to include three styles during the informed consent process. There are visual learners, auditory learners, and kinesthetic learners. The visual learner would want to see a picture, photograph, or some demonstrative example of what is being proposed. The auditory learner wants to listen very carefully to recommendations, the surgical procedure, pre- and postoperative instructions, reasonable expectations, alternatives to care, and inherent risks and complications. The kinesthetic learner is looking for how all of this affects them personally. The goal of informed consent is reaching high levels of understanding, which may be reached by combining all three learning styles throughout the process of informed consent. It is not a signed document itself, but the process of understanding documented by the consent. I believe the surgeon has a responsibility to outline the risks and hazards of the proposed procedure. It is also suggested to develop a team of surgeon, nurse, coordinator, and others to achieve this goal. There are some patients who never reach a complete understanding of the informed consent process and it is recommended that surgery then should not proceed. It is also recommended that multiple visits and discussions be utilized allowing appropriate time for discussions at home, reflection on goals, and adequate questions to be answered before proceeding with a nonemergent procedure.

Privacy law

Privacy law is intended to protect patient information. This includes their medical information, photographs, lab results and correspondence. HIPAA covers many protections for the patient. The practice has an obligation to explain and document the patient’s understanding and acceptance. There is a duty to secure their information, and even pursue those who violate such protections. The practice will have an obligation under new “red flag rules” to check identity of patients with their coverage, further protecting the patient against identity theft. The plastic surgery office must be careful when using patient information or photography in a commercial way, such as on a website, advertisement or patient outcome booklet, shown to prospective patients. A breach of privacy is not covered by your malpractice insurance and any judgments as a result of this breach must come from you alone and not your insurance company. It is not unusual to have a claim joined to a negligence claim that patient information was not protected. This often adds to the stress of a lawsuit and may add incentives to settle the claim. If you have patient

permission to show such information, a specific written consent for commercial use must be signed by the patient. You can help yourself and your practice by adopting HIPAA rules,¹ identifying a “red flag” office employee who can safeguard patient identity, and being very diligent about obtaining consent forms for treatment, release of information, specific commercial use and photographic consents. Areas of concern are thus social networks and blogs, such as Facebook and Twitter. There is risk of a surgeon or practice describing “a day in the life of a plastic surgeon” on a blog, but that day’s patient may recognize him or herself, even though no name is mentioned. There is metadata embedded within a photograph that remains despite a file name change. It is important to “scrub” or remove the metadata before posting or displaying any photograph even with specific written commercial consent. The metadata may become visible when a mouse is used to highlight a photograph even if named to prevent disclosure. The HIPAA consent for treatment and documentation such as photography is inadequate when the photograph is to be used to promote the surgeon’s website, even if for educational value. The specific commercial consent must list specific uses, length of time, where it is to be posted, and other distributions. It is also a help to seek a Communication permission from the patient outlining and documenting how they may be contacted, either by cell phone, texting, regular mail, at work or home or any type of social media.

Warranty law

Warranty law involves two specific types of warranty issues; “express warranty” and “implied warranty”. You should understand that warranty issues are not covered by your malpractice policy. An express warranty utilizes a demonstrative part of the record to create a guarantee towards a result. This can be accomplished by including a photograph that the patient brings of a result they seek, or it may change created results that are made a permanent part of the business record. It is well accepted among physicians that there are no warranties or guarantees towards a result, since healing can be so specific and usually out of the physician’s control. While the visual aids are important in educating the patient about procedures and expectations, the practice should be very careful not to establish a guarantee of a certain result. Patients seemingly have unrealistic expectations, as the media and other factors portray certain social appearances. Utilize all educational tools including imaging to help the patient understand the procedure and the results but make sure you have both a disclaimer and documented discussions concerning realistic expectations.

The implied warranty can be more difficult. This is not based on something added to the chart that is tangible but rather an understanding that the patient presents to you that you must consider and address. Examples might be the fact that two weeks after a major surgery, the patient is expecting to travel to a family or business retreat. There is a possibility that the patient reasonably may be able to attend such a function, but are you willing to guarantee they will heal appropriately to do so? This becomes the main issue of these implied warranties. The patient discloses a requirement that they present. You should be careful to disclose and document the many reasons that might interfere with their requirement. Possibly changing the date of surgery or other considerations

should be addressed. If nothing is discussed or documented, and the patient misses their major event, it could be judged as your fault and you would be responsible for any financial losses they incur. This is becoming more common, as patients seek and demand quicker recoveries, adding procedures at the last minute, all within a shorter and shorter timeframe. Implied warranties could arise from time issues, financial estimates and costs, future care and treatments, and issues concerning results and expectations. Make sure the entire office team discusses patient comments and interactions because it is not uncommon to have a patient disclose varied demands to a receptionist or coordinator and never mention them to the surgeon. Include a paragraph in your informed consent document as well as your financial agreement that no warranties express or implied are present and that the patient understands and agrees with this.

Product liability

Product liability issues cover the increasing number of products we distribute, utilize or prescribe. There are many areas within product liability that would expose the practice. Those arising from negligent use of a product may have claims falling within their malpractice policy. Other misuse of a product or altering a product by placing on your private label may elicit additional claims not covered by your malpractice policy. Any device, product, or prescription that is given to a patient should include full instructions, risks, hazards, and alternatives. A key factor in this area is that liability is created in the foreseeable stream of commerce. That is when you give a sample of a skincare product to your patient; it is foreseeable that they might share that with family members and friends. It therefore becomes important to provide good safety instructions as to its use, allergies if any, and concerns of treatment, and document those in the record. When their friend uses the product and has a reaction, you may be responsible, even though you have never seen the friend as a patient. Adding private labels to the product may hide important ingredients and instructions. You should be careful to maintain such important information. Altering the product, even as simply as putting your name on it, may eliminate the manufacturer’s responsibility to defend you for using it appropriately. Be careful and investigate what are FDA approved uses for the product and/or device. Be cautious when industry reps suggest a different use without providing you with written approval. A physician has the ability to prescribe off-label but some precautions are necessary. The three necessary elements for off-label use are: (1) that the product is approved by the FDA for use; (2) that the proposed use is not experimental; and (3) there should be written confirmation of the patient accepting and understanding the off-label use.

Fraud and abuse

Fraud and abuse can definitely turn a winnable malpractice case into one that has to settle or is lost. Fraud is defined as the intent to deceive and abuse is defined as the intent to confuse. There are multiple ways in which fraud and abuse can be a part of a plastic surgery practice. Not only can fraud and abuse have a very negative effect on the outcome of a malpractice case, but in many states, a fraud conviction can

both jeopardize your medical license and involve criminal activity. One way of avoiding the perception of fraud is to assure your medical billing and coding conforms to your operative record and treatment notes. It is generally understood that the codes used for billing can be changed as an ongoing process. You must be consistent when adjusting the billing codes to reflect ethically on the procedures and treatments performed. Another area of exposure to fraud is the medical record. Altering a medical record can also expose you to both civil and criminal penalties. There are many ways to disclose an altered record that you should be aware of.

One technique involves an ESDA test, which measures pressure indentations on a page. An ESDA (electrostatic detection apparatus) is a piece of equipment commonly used in questioned document examination, to reveal indented impressions on paper, which may otherwise go unnoticed. It is a nondestructive technique (will not damage the evidence in question), thus allowing further tests to be carried out. It is a sensitive technique, and has been known to detect the presence of fresh fingerprints. When writing is fashioned on a sheet of paper resting upon other pages, the impressions produced are indented onto those below. It is these indentations which are detected using ESDA, thus allowing a match of the original document to its source (such as a ransom note, or a threat to extort) to the offender's notepad.

Where two or more handwriting styles can be found mixed into a single document, and features of one handwriting style depart from the features of the other, ESDA can help reveal the differences in pressures employed between the individuals responsible for the writing samples, otherwise unified on a single exemplar. An indentation on the page below can be evaluated to show corrections, additions, and other information about writings. A hospital chart has the most recent chronology on the top with past recordings on the bottom. When the patient is discharged, the chronology is reversed with the earlier dates on top and later dates on the bottom. Consequently, if there is a pressure indentation on a later date's page, that entry was made after the patient was discharged, which is altering a record.

Another method of documenting record alteration is analysis of the inks used. Each ink is dated and it is possible to confirm suspicions by testing the date of a questionable record entry. Records are changed appropriately based on misstatements and incorrect entries. The proper method of correcting a medical record is to draw a thin line through the misstatement allowing readability in addition to making an entry contemporaneous to the correction date and time in the record. Both entries should be initialed and date and time confirmed.

A further example of potential concern occurs when multiple procedures are performed necessitating two operative reports. The patient has carpal tunnel syndrome and is seeking liposuction. Her insurance through her business is self-insured and the employee health representative is a gossip, so she asks you to not disclose the liposuction to her company. The appropriate course would be to dictate two operative notes and make reference about each within each. The hand surgery operative note would make reference to an additional surgery to be dictated separately. The liposuction operative note would confirm prior hand surgery occurred and this procedure followed. A question of fraud or abuse that is deceiving or confusing would be to have no reference of both

procedures, possibly suggesting the total operative time was for the hand surgery alone.

Fraudulent concealment is yet another type of fraud that can plague the practice. If false or misleading information is given to a patient that they have been relying on, a fraudulent concealment claim may be generated. The significance of this is that it still is fraud, there is no malpractice insurance coverage, and it tolls, or extends the statute of limitations. That means if there is a 2-year statute of limitations after which an allegation claim is not valid, a fraudulent concealment issue can remove the statute's effect and render the claim still valid. An example where this may occur is in a lesion that is excised on the back with frozen sections showing removal of a squamous cell cancer with margins free of disease. The permanent section, however, and the final pathology report show tumor at the superior margin. This information is not disclosed to the patient who develops a recurrence; files a lawsuit 1 year after the statute of limitations would have prohibited such a lawsuit. A fraudulent concealment claim allows the lawsuit to proceed.

"Qui tam", part of the False Claims Act,² has the federal government rewarding fraud whistleblowers. Basically, a disgruntled employee files a false claim lawsuit against you, the employer, citing fraudulent claims, and the US government joins the lawsuit, allowing the whistleblower to collect a percentage of any judgment or settlement. This emphasizes the need for appropriate, ethical billing and coding, as well as eliminating disgruntled employees from the workplace.

Contract law

Contract law should have a limited role in plastic surgical practice. It is suggested to have a work employment contract with independent contractors, physicians in the practice, and aestheticians. Such an agreement would cover work-related requirements, ethical and legal standards, confidential and HIPAA requirements and other safeguards to the workplace. It is not uncommon for an aesthetician, employed by the practice, to quit and take all of the confidential patient information to their next place of employment. This is a direct HIPAA violation and there is a duty to retrieve and protect such information. Having a protective clause in your employment agreement prohibiting such an act is a further safeguard. Some states, such as California and Colorado, allow arbitration clauses as part of their state-wide tort reform. It can be attractive to establish such an arbitration required agreement in advance of surgery but it would not be legal to remove the patient's right to bring suit. One can argue further that the more a contract is established with a patient, the more likely a breach of the contract can be claimed when the results do not equal the patient's expectation. Contract law would be more of a problem in descending results and care than tort or negligence law. The patient merely has to prove that the contract was breached and their expected results failed, to collect money, whereas in a negligence action the physician must be proven to have acted negligently, which is usually more difficult to establish. A breach of contract merely requires that a contract be established and a party failed to fulfill their end of the agreement. Damages are paid to fulfill the contract. A negligence claim, however, requires a party to be negligent as to a duty of care, and damages are paid to compensate for

the negligent act. Develop an office policy manual outlining appropriate and expected care, as well as restricted and prohibited acts. Utilize an updated employment agreement for staff similarly outlining required and prohibited behavior.

We are observing an increase in “contract” personnel, often in the form of aestheticians, or operating facility staff, etc. The practice should be careful here in establishing guidelines for such individuals. This should be covered in an office policy manual. Contract personnel are not employees, and should have their own liability, not falling under agency law. This means you cannot totally manage their daily work, or cover them with insurance like the other employees. The issue of “control” over their work product is an important factor in labeling them as contract personnel or an employee; not the language used in their agreement. You should continually check on their licenses, malpractice history, and quality. You can provide them with the tools to perform their work, but not control their work such as you would with an employee. The issue is whether you will be responsible for their alleged negligence should a claim be made. The independent contractor is liable for their own negligence, while the employee through Agency law is your responsibility.

Regulatory issues within the law

There are many regulatory agencies overseeing a plastic surgical practice. The HIPAA is established to protect patient privacy and medical information. The patient should sign an acknowledgment of their privacy protection, and this is kept in the patient’s file. There are obligations to safeguard against identity theft, known as “red flag rules”.³ The practice must identify an individual to record each patient’s identity and inspect for procedures, billing, and insurance correspondence, to assure appropriateness throughout. This can include possibly copying the patient’s ID, such as a driver’s license or passport, including a photograph of the patient, and checking the above documents so they match the practice’s care and treatment.

The Occupational Safety and Health Administration (OSHA)⁴ covers office supplies and equipment assuring safety in the workplace. All supplies should be labeled with appropriate precautions marked, as well as a log of emergency treatment, should an accident occur. The FDA controls manufacturers of devices and products and although does not directly oversee physicians, there are requirements necessary for off-label use. Off-label use involves the nonexperimental use of an approved FDA device or product in a nonapproved fashion. Such use should have a specific consent documenting off-label usage and acknowledging patient acceptance. The practice should be very careful to only purchase FDA-approved supplies and avoid the temptation from frequent internet and mail solicitation for supplies that are “just like” those approved. Such a purchase would be illegal and could make the purchaser and practice subject to civil and criminal charges. State medical boards as well as state nursing and other regulatory agencies outline appropriate care in the office. It would behoove the practice to inquire about new standards and guidelines that apply. Ignorance is no excuse for inappropriate behavior. State board actions describe who can do what in an office environment and with what degree of supervision. It is very important for all staff and physicians

in the practice to understand and comply with these rules. It is unwise to ask an employee to care for a patient when it violates state rules. An example would be an aesthetician who was asked to inject Botox® when the state prohibits anyone but a physician, nurse practitioner or physician assistant to perform such an injection. Another example is to have your laser technician treat patients with you, the physician, out of the office and the state requires direct supervision of such treatments by a physician. If there is a bad outcome of such treatment, or anything that would trigger an investigation; it severely damages any defense raised and could void malpractice liability coverage. The practice must be vigilant in keeping up with the each state board rule and regulation, and decisions that affect a medical practice, nursing practice and others who participate in a plastic surgical endeavor.

Agency law

Agency law encompasses those in the workplace and their interactions. It is a doctrine that the employer is responsible for negligent acts of the employee during the scope of employment or in furtherance of the business. Any negligent acts by an employee are attributable to the employer. It therefore becomes important for the employer to outline what is acceptable and unacceptable behavior, usually in an “office policy manual”. Supervision becomes important, as claiming that one was unaware of risky or negligent behavior is no excuse and will not defer blame. You should have been aware of risky or negligent activity. However, violating the office policy manual that clearly defines what should not occur may help protect the practice against a liability claim. The practice should make attempts to avoid harassment in the workplace while developing a good team for communication with patients. Problem employees should be addressed promptly following the office policy manual as to counseling, disciplinary action, and termination. There should be documentation as to how these issues are addressed so if an ex-employee challenges their dismissal, the practice can support the decision.

There are many employee issues such as embezzlement, disruptive employees, employees who “steal” patient information, and have disagreements about hours, vacation and daily routines. All should be covered in the manual. Embezzlement can be potentially avoided by having a dual system of checks, say accounts payable and receivables matched against bank statements. One employee responsible for both sides may be a formula for theft. Develop written policy for hours, telephone, smoking, vacation days, and patient interactions that everyone agrees with, and sign a kept copy. Have a confidentiality clause that forbids theft of patient information describing HIPAA violations and the requirement of the practice to pursue those who violate this clause. A common example is the aesthetician employee who leaves for another job and takes all of your patient data to the next job. HIPAA requires you to protect such data and make attempts to retrieve it.

Internet and “blog” defamation law

The internet has dramatically influenced the practice of plastic surgery. Patients e-mail us from multiple states and seek information about care. It seems that patients share their

experiences on many of the social networks. Generally, the internet can bring us additional exposure and patients, while adding significant risk and potential problems. Some basic guidelines concerning e-mails are not to answer out-of-state inquiries with any specificity that the prospective patient can rely on. Failure to follow this guideline may expose you to practicing in the state in which you have no medical license – a crime. This only applies to prospective patients with whom you have not yet entered into a doctor–patient relationship. The practice should develop generic answers concerning basic information to respond to the out-of-state resident. It is usually recommended to include a disclaimer, e.g., if your symptoms and condition worsen you should seek help immediately in your community. The ongoing correspondence between the practice and the patient should be copied and recorded in the patient's chart. Telephone texting should have a similar documentation in the patient's file. Much of ongoing communication today involves internet messaging and it behooves the practice to establish policies which make such communication a necessary part of the medical record.

Many practices wish to enter the social networking community such as on Facebook or Twitter, establishing blogs and plastic surgery updates. One has to be very careful not to violate patient confidentiality by disclosing private information about procedures. One has to take care and not even mention what procedure you are doing on a specific day, as friends of the patient who might believe that day is reserved for their friend are now aware of the specifics about the procedure, which is a violation. One way around such exposure is to utilize generic procedures that are not specifically tied to a given day and include patient safety issues, general patient instructions, and current trends of plastic surgery. The practice must maintain a high level of professionalism complying with the HIPAA and other privacy issues. The use of photographs for commercial education and internet website usage require a specific written consent acknowledging their use. This is separate from the general photography consent considered as a part of diagnosis and treatment. The same considerations are given for office photographs, books, and references displayed to other patients.

A recent troubling trend is blogging by patients against the practice. A patient may have a perceived problem and begins to write on a website or a blogging page their interpretation of the negative. This is clearly one-sided and may in fact not be accurate. Despite this, the practice cannot respond, due to the HIPAA, without a specific written authorization. This one-sided attack poses great concern. There are attempts to control patients' speech through copyright law, but many believe this to be either unethical or restrictive. It may be suggested to develop a non-patient-specific practice blog outlining complications, noncompliance, and high risk procedures, as a balance to these attacks. The first inclination would be to attack the blogger legally, however First Amendment speech permits such opinions. The attacker who creates a fake website mimicking the practice is confusing and misrepresenting to the public, and may be subject to a lawsuit if you can identify and find them. Another suggestion is to utilize the internet search engines to place their blogging page on the second or third internet page, thereby reducing visibility. This will often lead to "games" where each attempts to manipulate the other, resulting in an extortion demand for money to

remove the blog. These actions by disgruntled patients have damaged many practices and threatened more. Attempts are being made to better control blogging sources in an effort to make this more fair and balanced.

Basic actions of a malpractice lawsuit (a guide)

There are many stages of a malpractice lawsuit. They include notice, discovery, pretrial motions, trial, and aftermath. Notice of the intent to file a lawsuit is controlled by each state with a required timely response by the physician or practice. Notice is usually provided certified for by a delivery service and must be taken seriously. As soon as notice is received, secure the medical records, and notify your malpractice carrier. Fight the urge to add to the medical record or alter it in any way. Obtain copies of the medical record from hospital facilities as well as your own office record. It may be wise at this point in time to ask employees as well as yourself to write a recollection of the patient's care and treatment with key words used prior to such writing, on advice of counsel and on anticipation of litigation. A life of a lawsuit may be over five years, and remembrances get lost over time as well as employees leaving. It is therefore suggested that, "on advice of counsel", each employee and physician in contact with the plaintiff write what they remember and keep these writings separate from the medical record. Keep these writings privileged and available only as an attorney–client work product, which the other side should not obtain. Keep these recollections separate from the medical record and under lock and key. There will be requests for medical records from the plaintiff and your malpractice carrier. You should have meetings with your carrier's agent and the assigned law firm. Usually notice is not the actual lawsuit but the intent to file a lawsuit should a settlement not be reached. Your carrier, attorney and you will discuss the case in depth evaluating the facts, standards of care, and defensibility. Once a lawsuit is filed, your team will develop an answer within the timed requirement and the process begins. Follow your hospital and facility by-laws, which might require notification of such a lawsuit.

The next stage is discovery. Discovery includes responding to written questions called interrogatories, and depositions to record testimony for future use. This process may take a number of years. You should remember to never respond to any such request without your attorney's input. You will have noticed your deposition well in advance and utilize the time to prepare at length with your attorney. All parts of discovery, such as depositions, require advance written notice of time and place. This allows one to prepare, collect information from the record, and seek consultation with legal counsel before actually providing the deposition. I would recommend you prepare with a senior attorney rather than the most junior associate. While you are quite comfortable in the operating room, the attorney is more comfortable taking your deposition. You must prepare by expecting certain questions, disclosing all concerns to your attorney, and understanding the process of the deposition. Once all the facts are gathered, a trial date is scheduled – make sure to block your calendar and devote the appropriate amounts of time for preparation. The pretrial stage includes demands from each side for exclusions,

expert testimony, and other concerns about your case. Frequently, arbitration or mediation is recommended by the court. A failure to reach settlement brings the trial date to schedule. The trial itself may take 1–2 weeks, depending on the complexity of the case and the court's schedule. You should plan on being there every day, following the advice of your counsel, being extremely respectful of the process and visibly concerned and gracious. The defense has two experts, while usually the plaintiff only one. You are your case's best expert and an additional expert is hired. Work with the expert and your attorney to win your case. It may be wise to travel with your attorney when taking the deposition of the plaintiff's expert as you may provide valuable on-site information to assist in their deposition. You will not be reimbursed for such travel, but the value to your case may far exceed your expenses. The last stage may involve appeals and other judicial and legal maneuvering, pending the outcome of the trial.

Aesthetic practice liabilities

The aesthetic plastic surgery practice has specific risks inherent to this area. Patient expectations are paramount to achieving desired goals and limiting risk. A disturbing trend is the lack of patient accountability combined with an unrealistic set of goals. It appears that any inherent risk or complication generates a legal concern even if fully disclosed in an informed consent document. More than ever, patient selection and appropriateness of procedure is important. Patients often demand certain procedures and the practice should be careful to assure the proposed procedure is an appropriate fit for this specific patient. Many believe it safer to create a more specific informed consent document listing the additional risks of such patient demands. The problem with this is that you may create additional risks by outlining such in a consent document. The ultimate responsibility of patient acceptance is yours and no document will protect you against an inappropriate decision. Smoking continues to be a major source of liability, as it affects healing as well as scarring and overall recovery. Adding additional risks to the consent is a good example of not avoiding liability where a better choice would have been not to accept the patient. Trends toward more mini procedures, while desirable for the patient, may not achieve the desired goals. Breast surgery continues to be the lead of malpractice claims, with augment mastopexy the majority. Any delay in healing, poor scar, or shape often leads to a lawsuit. Other trends concern where the surgery occurs, as questions arise after lengthy surgery in an outpatient setting. The balance between appropriate procedures, facility and anesthesia versus cost continues to be an issue.

Cosmetic medicine has assumed a lead in number of procedures performed and must follow general guidelines for risk prevention. Each skincare treatment, toxin injection, and filler injection should have a consent document. Additional concerns about who provides the treatment should follow state law, be it the medical board of the state, nursing board of the state, or skincare aesthetician governing body of the state in question. Establish patient care guidelines and follow them throughout the practice. An example might be: a patient for IPL treatment who, despite being told not to get a suntan, comes in for a treatment with a tan. It is wise not to treat the patient, despite their anger or demands. It is suggested that

you see prospective patients at least twice preoperatively allowing time for questions and procedure refinement. Include financial agreement discussions about costs of the proposed procedure as well as future costs, especially if a complication occurs. Develop a team to both address the patient's needs as well as discuss appropriate procedures and treatment plan. Recognize today's social pressures and media influences to present options to the patient that are realistic for the physician to achieve their goals. Try and avoid gimmicks and competing with unrealistic choices to keep the patient in your practice.

Managed care liabilities

The distance between aesthetic surgery and managed care/reconstructive surgery is narrowing. Patients have as many demands and unrealistic expectations for reconstructive surgery as they may exhibit in aesthetic surgery. The practice should present realistic options and procedures to the patient and after a clear understanding and acceptance, proceed with treatment. Additional concerns may arise with managed care coverage, and these should be addressed with the patient with good documentation. Your authorization letter should be honest, complete, and represent the facts and why treatment is medically necessary and appropriate. As you know, it is not uncommon to receive a denial, but remain a patient advocate and appeal as appropriate and necessary. The practice should be careful in not discussing fees with competitors, as this could violate antitrust laws. If you provide service through an emergency room, and not on the patient's managed-care panel, attempt to see the patient postoperatively without charge and document their satisfactory progress.

The Affordable Care Act creates liability on the physician even though a PA or nurse practitioner may actually see the patient. If the expected volume of patients become involved in care, physician interaction for all patients becomes impossible. There will be delays in treatment as well as rationing of care. It behooves the physician to establish criteria for treatment and a direct supervision method to assure appropriate care for all seen under the physician's umbrella.⁵⁻⁷

Liability carrier's issues

The choice of carrier providing your malpractice insurance is a critical one. Inquire as to their financial stability, track record, coverage inclusions, claims made or occurrence type, opportunity for purchase of a tail, and contractual decisions about settling claims. There is an increase in state board complaints and ask whether representation is included in their coverage. Check on which law firms represent physicians through the carrier and how responsive they are to the physician. It is not only the premium that should affect your choice. Many physicians have paid a very low premium only to subsequently find out the company is bankrupt and they have no coverage at all. There are carriers common to plastic surgery that are active within our societies and understand the nuances of a plastic surgical practice. Determine your limits of coverage based on your practice, hospital privilege, and risks and exposures. The level should be appropriate to maintain hospital and facility privileges, yet not excessive, helping to make

you a target. Evaluate companies that encourage discussion about problem patients while not considering each inquiry a claim. Look at their rating and past record in a plastic surgery arena.

Legal issues in physician partnerships

A higher percentage of physicians are associating with partners than in the past. It becomes important to understand the legal implications of such arrangements. There are many types of associations from full partnerships, office-sharing arrangements, limited liability partnerships, single specialty groups, and multi-specialty groups. One considering such an association should seek input from their accountant, attorney, estate financial planner, family, and compliance with their business plan. Spend considerable time with the individual you seek to join or associate with. It is amazing how often what started as a great idea of like minds ends up with exasperation in being so different in goals and style. Make sure you complement each other, and can retain some of your autonomy and individualism, important to a plastic surgery mindset.

Whatever format you choose, establish a communication mechanism, as well as a conflict resolution format. The best of intentions can rapidly go downhill without continuing to “make it work”. Have legal counsel work with your business plan to make it equitable and yet protective to both/all parties. All aspects of the arrangement must be considered, especially financial, and termination issues. The agreement is a binding contract and must reflect *all* considerations agreed upon. There should be no verbal or handshake addendums that are not included within the pages of the agreement.

Issues to consider and resolve are:

1. Ownership – office, equipment, other investments, and the right to make decisions about new and past expenditures
2. Duration of the agreement, including renewals, termination, and adjustments
3. Duties and expectations of each party should be carefully defined and described
4. Financial allocation of expenses – fixed (rent, employees, leases, personal expenses, e.g., pager, etc.), variables based on collections (medical supplies, office supplies, etc.)
5. Ethics – defining standards (ASPS, ACS, state board, federal), malpractice requirements
6. Termination process – who gets what, staff issues, costs involved, e.g., to copy records, etc.
7. Hold harmless clause – adding staff and physicians’ decisions, management of office
8. Accounts receivables (always difficult) – possibly a trust established by senior associate keeping funds collected by junior associate, but in name of junior associate, only released when agreement and liabilities are resolved
9. Financial considerations – bonuses, salary, advances, etc.
10. Confidentiality clause
11. Marketing; advertising
12. Ownership of telephone number, name, etc.
13. Restrictive covenants – can and will be enforced as long as “reasonable” as to time, description, and distance. So,

a restriction for the practice of medicine for a period of 5 years in the entire city will probably not be enforced. However, a restriction for the practice of plastic surgery for a period of 1 year within 5 miles of every office location currently used probably will be enforceable. Another option is to consider a “liquidated damages clause”. This acknowledges the difficulty in enforcing such restrictive covenants, and in advance, arrives at a money settlement (e.g., \$150,000) that the leaving doctor must pay the other doctor for breaching restrictive covenants. This amount may be withdrawn from accounts receivables due to the leaving doctor or other arrangements that are enforceable.

There are many more considerations necessary for a successful association, despite the legal structure. The most important is perceived fairness and ongoing attempts to keep it positive, efficient, and responsive to the many changes and challenges affecting the plastic surgery practice.

Patient selection

Patient selection has become the most important part of risk protection as well as practice building. There is a disturbing trend of less accountability in the patient and an approaching “must be perfect” expectation for the practice. Lawsuits have been filed by patients who develop a known inherent risk of a procedure, despite having good documentation about such risks in advance. Lawsuits have been filed even with poor patient compliance, even when discussed in advance of how important this is. It approaches a mindset that any inherent risk or complication must have been the result of “something done wrong”.

The key to limiting this is to choose patients you feel you can trust and those for whom you can realistically reach their expectations. It is wise to see the patient more than once pre-treatment to assess their goals and expectations, as well as how they interact with you and your staff. In tough economic times, it is difficult to say “no” to a patient, but “no” is much preferable to defending a malpractice lawsuit. Be realistic in approaching your choices of procedures. Patients are becoming more specific-procedure driven, rather than issue driven. They might come in asking for a facelift, when in fact other choices might be more beneficial and appropriate. We should educate them and understand we are responsible for the choices made, not the patient. We are the experienced physicians and our role is to protect and guide the patient, sometimes protecting them from themselves. It is not appropriate to grant the patient’s desires unless they are appropriate and achievable. There is a difficult defense in a malpractice suit when the defendant physician states “the patient wanted this procedure and signed all the informed consent documents indicating greater risk”. The physician has the task of approving procedures, not the patient. The patient cannot appropriately consent to an inappropriate procedure. The surgeon should have either rejected accepting the patient or suggested an appropriate procedure. There is distinct added liability from not following this principle.

Dr Mark Gorney developed a “GorneyGram” that helps physicians assess realistic goals of the patient (Fig. 6.1). It balances the deformity present against the effect such a

Fig. 6.1 Dr. Mark Gorney developed a “GorneyGram” that helps physicians assess realistic goals of the patient.

deformity has on the patient. For example, Quasimodo, the hunchback of Notre Dame, seeks contour corrective surgery. He states anything you can do to improve things would be great. Quasimodo would be on the bottom right of the GorneyGram; a good place to be. Another patient with a minimal small 1 cm scar on her lower cheek from chickenpox cannot leave the house without covering it to extreme. This patient is in the upper left area of the GorneyGram; a most dangerous place. Likely, nothing you can do will help the patient to her acceptable level. There should be an assessment of all patients to see where they lie on this scale. Some areas will change over time, but it is amazing how accurate this is overall in helping to define which patients are better candidates for your care.

Electronic medical records

The Affordable Care Act has increased the requirements to utilize electronic health records (EHR), but with an increase in patient complaints and claims. The necessity of documenting on a computer or tablet can remove the face-to-face interpersonal contact with the patient. It has been well accepted that patients are less likely to bring a medical negligence claim against a physician they like. Often the doctor’s mind is focused on a computer and not on the patient, becoming an obstacle in the doctor–patient relationship. It is suggested that a routine is developed in which a direct interpersonal discussion with the patient begins, and only after a relationship is established will after an apology in needing to document this examination and treatment the doctor focus on appropriate documentation. This new paradigm is a learned behavior and some practice may help achieve the proper balance between correct documentation and a personal visit. The second area of risk associated with EHR is the “smart text” developed for each specialty to facilitate data entry and speed up the required time. The default data developed by the programmer, usually along with the physician, must be checked to assure it is correct. It might be easier to utilize

default smart text phrases but, if incorrect, this sets up the physician for liability. The physician exam with “No masses seen” as a default text must reflect the reality that no masses were seen. It is suggested that the smart texts are reviewed for accuracy and inclusion. Once signed, you verify the correctness of the medical record. If such entry is incorrect or false, your credibility in the courtroom is questionable. The third area of EHR concern relates to privacy issues. An aesthetic patient seeks a breast augmentation and liposuction. She demands that this surgery remain private and is not to be shared with anyone. No insurance is involved and therefore no fraud issues arise. However, in a health system all the data from her surgery is in the EHR for the next physician to observe. I am not aware of a mechanism to restrict such data, preventing viewing by future physicians unless the patient approves or it is necessary for care. I would explain this to the patient. Even though they seek confidentiality, their EHR record will include all surgeries they have experienced. HIPAA should prevent subsequent healthcare providers from disseminating such information, but patients have become angry at their plastic surgeon when a family practice physician discusses their breast augmentation and the patient believes you were told to keep it private.

Summary

There are many legal interactions and risks within a plastic surgical practice. One should be aware of these risks and develop standards of protecting the patient, practice, and physician. I would suggest attempting to keep up with the changing medico-legal environment by attending risk courses; explore state medical board rule changes, and the plastic surgery societies’ panels. Establish relationships within the legal community as your practice grows. This will become a useful resource for questions that arise and have a positive impact on the medical malpractice arena. Understanding all of the above is important, but the most important risk protection is appropriate patient selection. Choose patients you like and feel you can trust, and develop a relationship. Match the chosen procedure with their expectations and follow them as you would want to be seen if you were the patient. Develop a team that reflects your attitude and caring for the patient.

Digital imaging in plastic surgery

Daniel Z. Liu and Brian M. Kinney

Access video lecture content for this chapter online at expertconsult.com 

SYNOPSIS

- Photography is not only useful, documentary, collaborative, didactic, medical-legal, a research tool and even promotional – it is standard of care and a *sine qua non* for proper practice in plastic surgery.
- Our specialty is highly visual and relies on accurate representation of form, as well as function, to diagnose, plan, treat, evaluate, and track patient surgical outcomes.
- The photographic record contains much more information than can easily be documented in words, including color, tone, texture, shape, vascularity, bulk, spatial relationships of anatomic structures, global aesthetics, aging, and historical changes, to name only a few.
- The value of images increases with time.
- Technological advances in videography and three-dimensional surface imaging in plastic surgery may improve communication, education, and patient satisfaction.

Purpose

The first principle of photography as a medical record is to document the pre- and postoperative condition of the patient, serving as an accompaniment and function analogous to radiography. Preoperatively, the record is a guide in evaluating the patient's condition, highlighting relationships of the anatomy, and demonstrating aspects of physiologic function for tissues like the nose, eyes, mouth, and hand. Postoperatively, images record changes for patient teaching, self-evaluation for retrospective review, and assessment of results *vis-à-vis* planned outcome. Intraoperative imaging may feature key aspects of the surgical procedure.

Much of plastic surgery rests in an unusual setting in medicine. The core and history is reconstructive in nature, largely born from efforts to rebuild injuries sustained by First World War soldiers. Whether reconstructive or aesthetic, its essence is to restore form and function, and today, a great portion is neither urgent nor critical to immediate health. Instead, much is elective and focused on quality of life,

especially in the aesthetic arena. Reviewing photographs with a patient may transform the preoperative planning from an interaction tilted one way from the doctor *to* the patient. Instead, the effort may be collaborative and consultative, an interaction between the doctor *and* the patient.^{1,2} Various scenarios can be examined and evaluated with digital imaging, modeling and morphing. Care must be taken when showing potential postoperative results, to avoid the implication of an implied or guaranteed result.³ One popular software program (Mirror Image)⁴ contains an important default disclaimer, "Simulation only: Actual results may differ."

The didactic nature of medical photography cannot be underestimated. Decades ago, sketches were used, followed by black and white photography, color transparencies and film, with the modern progression to digital images in the last 20 years. For all practical purposes, analog photography is a niche market, and digital imaging reigns supreme. Between the consultation and the operative procedure, planning requires good recall and representation of the anatomy. The images serve to refresh the memory of the surgeon. In addition, it is critical for patients to understand excesses or deficiencies of tissues, issues of symmetry.³ Features of their anatomy may facilitate or hinder surgical planning, influence choices in surgical approach, affect risks of complications, compromise or augment patient satisfaction. Patient teaching requires proper photographic representation of the preoperative condition and explanation of the changes achieved with surgical intervention. The evolution of a surgical practice can be tracked most easily over a period of years through systematic inspection of imaging of the patients' condition through the course of their diseases or conditions. A particularly common phenomenon is for a patient to not recall how they looked before surgery when critically viewing the postoperative result. Occasionally in reconstructive procedures and more often in aesthetic ones, the patient's psychological "set point" is re-established at their current condition, and the desire for further enhancement leaves them with falsely elevated expectations. Photos are indispensable in this setting and may provide reassurance that goals have been reached.

Maintaining proper images and systematically evaluating them postoperatively can only improve awareness of surgical choices and outcomes. Properly preserved analog images may last decades with original fidelity and 100 years or more with mild degradation. Digital images may not last much longer. Challenges in the evolution of technology lead to viewing problems (incompatibilities in hardware), scrambling issues (changes in compression algorithms), inter-relation limitations (expired webpages or hyperlinks), custodial problems (where the data resides), translation issues (how to read old storage with new technology) to name a few. If digital concerns are solved, images could last centuries or more.⁵ Building a digital database and engaging in periodic data mining is a core component of self-improvement in clinical care. The advent of digital photography eliminates concerns about lack of space, difficulties in storage like degradation of image quality, the ability to compare past and present results over large series and related issues. However, they are subject to their own vagaries. Old retrieval technologies (floppy disks, CDs, etc.) are subject to catastrophic failure. For example, a scratch on a transparency may slightly degrade the quality of the image, while the same event in a digital image may make it unreadable. Digital images must be backed up, and the methodologies rapidly change necessitating continual hardware upgrades. The best storage methods have changed 5–10 times in the last 20 years from floppy disk to magneto-optical disks, magnetic tape back-up, compact discs (CDs), digital video discs (DVDs), USB flash drives, portable hard drives, network attached storage drives, and more recently, “in the cloud” at a remote data storage center on the internet. Much like the evolving standards in business and research regarding storage of e-mail and digital documents for potential legal cases, our *de facto* standards dictate that photographs must be preserved, organized, properly referenced and identified, while easily retrievable.

Informed consent is a key part of medical record-keeping, and photography is essential to proper medical records. Almost every patient understands that photographs are part of the medical records. In fact, many insist on seeing “before and after” examples in their initial consultation, the best time to establish the necessity of accurate documentation. Some patients have a strong need for privacy; however, most surgeons will refuse to operate on a patient who refuses medical photography. Patients understand they have control and options on how their pictures will be used. Some practices allow only internal records in their private chart, others may permit sharing with other patients in consultation without identifying data, and some are comfortable with unrestricted use on the internet, in print, and television advertising. A thorough, detailed consent form specifically for the use of images is necessary for a proper medico-legal record.¹ Consent forms from the American Society of Plastic Surgeons are available for member surgeons.⁶ Photography’s utility as a research and interpretative tool in our field is without question.⁷ Comparison of how our journals have progressed from the first decade of the 20th to the 21st century shows that our journals have gone from black and white to color photographs, to online digital images in low and high resolution, to online video. Three-dimensional simulations that allow a “fly through” of the anatomy have been available for several years. Information density in images is an order of magnitude greater than the written word. With decreasing costs in the digital era,

increasing use of imaging improves learning and documentation. In coming years, widespread use of artificial intelligence for image processing will likely allow for digital data mining of the image content itself. This would be a major advancement beyond assigning database attributes to digital files like age, preoperative and postoperative photograph dates, type of procedure, etc. Instead, we may begin to see digital reference to quality of outcomes, conditions of anatomy on validated grading scales, etc. Even now, consumer digital cameras and photography software have “face finders,” automated red-eye reduction and similar tools. Professional systems have capabilities like automatic pore evaluation on the skin and cell counters for microscopic work. One could imagine many future potential applications like automatic color detection, evaluation of cutaneous vascularity, flap perfusion and others.

Since the mass “migration” to the internet by the general population, the public has turned online to research plastic surgery, compare results, investigate complications, nurture special interest groups and procedures, and engage in promotion and marketing. There are many egregious examples of excess, manipulation and deception; however, there are even more beneficial opportunities for patient education, practice marketing, advocacy and public health outreach. In addition, surgeons often disregard photographic documentation standards of care.⁸

Standards in capturing images

Little has changed for the framing and composition of images since Morello *et al.*⁹ and Zarem,¹⁰ and many before them specified these aspects of photographic standards in plastic surgery. However, many other factors have evolved in the transition to the digital world.¹¹ Key principles must be followed.¹² Consistency in results is affected by numerous factors.^{7,9,10,12} Facial photographs are taken at the 35 mm camera 100 mm lens digital equivalent, while body images are taken at the 50 mm lens equivalent.¹³ Shadows should be avoided. Colors must be natural. Lighting should be unobtrusive and consistent. Standards must be obeyed.^{14,15}

Digital image characteristics

Many variables affect images, and many are in the control of the plastic surgeon. Parker *et al.*⁷ have documented four basic ways in which inconsistency is introduced into photography: (1) photographer-based; (2) publisher-based; (3) combined; and (4) patient-based. Category 1 in their scheme includes view (composition), background and zoom, which are generally consistent among journals. Publisher-based criteria, size and image labeling are less problematic. Combined criteria, color, brightness, contrast, and resolution vary in published journals. Category 4 criteria: clothing, accessory apparel, make-up, facial expression, and hairstyle, are designated as patient-based, but are substantially under the control of the photographer. A dark-colored “collar” drape can be used over the shoulders for facial photographs. Accessory apparel should be removed, as make-up, false eyelashes, and similar accoutrements of fashion may interfere. Hairstyle can be mitigated by using standardized hairbands or ties. Patients can be coached to maintain neutral facial expression.

Galdino categorizes factors into direct and indirect.^{11,12} Direct variables include lens, viewfinder, digital chip, resolution,

Key principles

- The same camera and photographer should be used. Changing a digital camera (and therefore the color and white balance) essentially alters the pixel resolution, photonic sensitivity and hardware image processing.
- Shutter speed and aperture must remain the same. Positioning of the patient and photographer in the room should not vary.
- Guide marks on the floor may be required; flash equipment and lighting should not vary.
- Adequate lighting is essential. Shutter speed should be at 1/60 of a second or faster.
- On digital cameras, keep the magnification factor comparable with a 35 mm camera 100 mm lens for essentially all images except full body views, where a view comparable to a 50 mm lens may be used.
- Focus by moving the camera closer or farther from the patient and note the position of the mechanized zoom lens barrel in relation to the camera body.
- Do not change the white balance, and keep it in sync with the lighting used (often flash or fluorescent) on a medium blue background.
- While modern cameras often contain 16 megapixels or more, generally more than 6 megapixels are not required.
- Space for digital images is not an issue in this era of terabyte hard drives, and the speed is easily adequate for rapid access of data.
- More images than will likely be used in a career can be stored on portable drives.

compression and software algorithms of the camera. Indirect are listed as lighting, metering, depth of field, color temperature of lighting and output method. Both categories are easily controlled by retaining consistent techniques from visit to visit (see [Key principles box](#)).

Background

Medium blue or 18% gray featureless backgrounds provide the best skin tones and affect exposure least. White or black backgrounds affect exposure on the most commonly used camera setting (matrix metering), so the mode must be changed to spot mode metered on the skin in the center of the field. However, the sharp contrast will not create a natural skin coloring. Standard blue towels used in surgery are close enough to ideal to be used without problems, but green surgical towels are not.

White balance

Accurate, lifelike color reproduction is dependent on neutrality, an equal distribution of colors in the white, gray and black in the image to ensure accuracy of hue. A color-balanced image contains all hues in equal proportions of illuminating white light. Unfortunately, different types of reference white points exist in various environments. Indoor scenes lit by incandescent lamps are distinctly different from daylight. Fluorescent lights come in various shades of blue. Operating room lighting is variable in color, temperature, angle, and distance from the

patient. The white balance adjustment attempts to capture neutral colors by compensating for these changes. Modern digital cameras have numerous settings like daylight, fluorescent 1 and 2 (or high and low), and auto white balance, among others. The auto white balance setting is often misled by the pulsations of overhead fluorescent lights and may produce variations from image to image. Flash lighting minimizes the effect of ambient light and forces the use of smaller aperture, lower ISO, and shorter exposures. Ideally, a multiple flash system in a dedicated photography studio is used to eliminate these problems in order to capture flesh tones consistently and accurately. Single on-camera flash is inadequate due to shadowing effects in all backgrounds except black.

Lens aperture and shutter speed

There is a delicate balance among aperture, lighting, and shutter speed. A narrow aperture (high F-stop) provides increased depth of field compared to a larger aperture. Too wide an aperture (low F-stop) allows for a shallow depth of field, which creates difficulty, for instance, in capturing simultaneous changes in the crow's feet area and the submentum. An F-stop of 16 or less should be used, with consistency maintained over pre- and postoperative settings. Skin with darker pigmentation may require a larger F-stop.

Shutter speed controls the amount of time that light is exposed to the image sensor. Increased shutter speed allows less light in, while decreased shutter speed results in blurry images with subject movement.

Composition and positioning

Full face

In the anterior–posterior (AP) view, the superior border of the head must be framed by a small amount of background, about 10% of the vertical height of the image or 2 cm above the vertex of the skull. The inferior border of the image should stop just below the suprasternal notch. The Frankfort horizontal plane connects the infraorbital rim to the tragus and is kept parallel to the floor. For the frontal view, the ears can be used to ensure proper positioning. In the lateral view, the patient's body and head should be facing 90° from the focal plane of the camera. The eyebrows should be superimposed. While some cropping of the occipital region is acceptable, in general, lateral views should include the full view. Oblique views should be taken at 45° and, in this view, the tip of the nose should protrude slightly beyond or rest just at the contour of the distal malar eminence. Five standard views are taken, an AP, two oblique and two lateral, right and left for each of the latter two ([Fig. 7.1](#)). When indicated, the malar eminence may be imaged, generally the bird's eye view is preferred over the worm's eye view, unless a particular feature of anatomy is involved.

Musculature should be relaxed in all photographs unless otherwise specified.

Eyes

The same five image views (anterior, two laterals and oblique views) are part of the basic set for the eyes. Close-up images of the eyes should include a small border of forehead skin above the eyebrows and extend inferiorly to the upper lip at the nasal spine. For the lateral and oblique views, positioning

Fig. 7.1 Full face. Five standard views: (A) Anterior–posterior. (B) Right oblique. (C) Right lateral. (D) Left oblique. (E) Left lateral.

is similar to the views of the head honoring the superior and inferior borders herein. Additional views are essential and include the following at a minimum: (1) closed eye view to highlight the superior tarsal sulcus and fold, and (2) upward gaze to highlight inferior orbital fat pockets and the lower lid margin. A squinting view consists of open eyelids with contracting of the superior and inferior orbicularis oculi to feature the impact of muscle action on eyelid shape and function. Occasionally, a view with tightly-closed eyelids to highlight the orbital orbicularis, zygomaticus muscles and others is required for certain surgical procedures (Fig. 7.2).

Glabella

Images of the corrugator muscles may be taken at rest and on full contraction to document wrinkling on the validated four-part glabellar rhytid scale (Fig. 7.3). Full face images are often used; however, the superior border is best cut off at the location (or former location in baldness) of the anterior hairline and the inferior border is often positioned midway between the radix and the tip of the nose on a horizontal line through the lower margin of the malar eminence. The closer view provides more detail of pore size, eyebrow position and skin texture. Oblique and lateral views are generally not necessary.

Nose

The superior margin of the nasal view is essentially the same as for the eyes – just above the eyebrows. However, the

inferior margin is at the upper lip or between the closed lips. In addition to the five basic views, worm's eye view or chin-up view is included (Fig. 7.4). The superior and inferior borders are the anterior scalp line and the mentum, respectively. When muscular release at the dorsum or nasal spine is contemplated, dynamic pictures of contraction should be included.

Lips, nasolabial folds, and mentum

The superior border is on a line just above the nasal tip and includes the alar base, while the inferior border allows a small amount of background to show below the chin (Fig. 7.5). The lips should be slightly parted to detect features in the mucosal surfaces near the intersection of the upper and lower borders. When injections into vertical lip lines are performed, the pursed lip or orbicularis-contracted view is added. Additional views may include contraction of the mentum when toxins or soft-tissue fillers are part of the therapeutic intervention.

Dental occlusal views

When intraoral or two-jaw surgery is considered, dental occlusal views are required, and transparent cheek retractors must be utilized.

Ears

Adequate visualization of the ears requires that the hair must be retracted. Anterior and posterior views should include the

Fig. 7.2 Eyes. Standard views: **(A)** Anterior–posterior view. **(B)** Anterior–posterior view with upward gaze. **(C)** Anterior–posterior with eyes closed gently. **(D)** Anterior–posterior with eyes closed tightly. **(E)** Right oblique in forward gaze. **(F)** Right lateral in forward gaze. **(G)** Left oblique in forward gaze. **(H)** Left lateral in forward gaze.

Fig. 7.4 Nose. Standard views: (A) Anterior–posterior. (B) Right oblique. (C) Right lateral. (D) Left oblique. (E) Left lateral. (F) Tilted head view.

Fig. 7.5 Lips, nasolabial folds and mentum. AP view: (A) Pre- and (B) post-procedure. Right oblique: (C) Pre- and (D) post-procedure. Right lateral: (E) Pre- and (F) post-procedure. Left oblique: (G) Pre- and (H) post-procedure. Left lateral: (I) Pre- and (J) post-procedure.

full head and supplemental mid-range views should extend from the upper neck to above the occipital ridge to bring the ear more fully into the image. Lateral images should include close-up composition with the vertical height roughly twice the height of the ear itself.

Chest and breast

Variations in the configuration of the trunk dictate that the principle of bordering the image based on regional anatomy is critical in these images (Fig. 7.6). Vertical borders should range from above the suprasternal notch in the lower third of the neck to below the mid-costal margins. Patients should be disrobed above the waist, and all visible jewelry must be

removed. There are three basic variations in arm positioning on the lateral view of the breast: (1) arms at side; (2) arms on hips; and (3) arms behind the lower back. The most common, in the author's experience, is the former. Oblique views may be taken in positions 1 and 2 above, while occasionally AP views are taken with arms above the head. Dynamic pectoralis animation deformities may be highlighted on AP views with hands pushing against the hips.

Lower trunk, abdomen, and buttocks

The five standard views are supplemented with a posterior view (Figs. 7.7, 7.8). When the buttocks are the focus of the image, no panties are used. It is essential to use disposable,

Fig. 7.6 Chest and breast. AP view: (A) Pre- and (B) post-procedure. Right oblique: (C) Pre- and (D) post-procedure. Right lateral: (E) Pre- and (F) post-procedure.

Continued

blue paper photographic panties (“modesty garments”) to standardize the clothing, color and white balance. Almost invariably otherwise, a patient would arrive on a subsequent visit with different color, contour and texture of undergarments. In addition, sometimes patients will arrive with a distracting, different dark-light tan line in summer climes. Legs should be slightly apart to allow viewing of the groin against the light background. Feet should be aligned with appropriate tape marks on the floor.

Lower extremity

The five standard views should also be supplemented by a posterior view (Fig. 7.9). The patient should stand comfortably erect with arms folded above the chest. Feet should be approximately shoulder width apart, aligned with appropriate tape marks on the floor. For a full view, the upper margin should be found at the level of the umbilicus and the lower margin inferior to the toes or heel depending on the view. For the half upper or lower view, the lower or upper margin, respectively, should be just below the knee at the level of the

inferior popliteal fossa or just above the patella. The photographic background must extend onto the floor, all the way out of the frame for the lower view.

Hands and feet

A full dorsal and volar view is required. In some patients, oblique views are required as well. Dynamic views in flexion and extension are an essential component of the complete medical record (Fig. 7.10).

Specialty views

Other regions of anatomy follow the same principles: (1) clear margins of background or adjacent anatomy; (2) AP, lateral and oblique views; (3) dynamic views as indicated; and (4) macro views when required to demonstrate features of anatomy.

In the hospital and operating room

The compact digital camera has largely supplanted the 35 mm film camera in the emergency department and on the go.

Fig. 7.7 Lower trunk, abdomen and buttocks. Standard views: **(A)** Anterior–posterior. **(B)** Right oblique. **(C)** Right lateral. **(D)** Left oblique. **(E)** Left lateral. **(F)** Posterior view.

Fig. 7.8 Lower abdomen, buttocks, and thighs. Standard views: (A) Anterior–posterior. (B) Right oblique. (C) Right lateral. (D) Left oblique. (E) Left lateral. (F) Posterior view.

Fig. 7.9 Lower extremity. Standard views: (A) Anterior-posterior. (B) Right lateral. (C) Left lateral. (D) Posterior view.

Results are excellent, and convenience is high. However, when expense is not an issue, many surgeons prefer SLR-like full-frame (35 mm diagonal) digital cameras in the operating room. Operating room lights vary among hospitals and rooms. On-camera hot shoe flashes for large format cameras are of much higher quality than built-ins for compact cameras. This allows for consistency in color balance, as ambient light does not provide the illumination for the exposure. Flashes that are designed for medical photography include the ring flash, dual-point flash, and the ring and point combination flash. The ring flash is particularly useful for intraoral anatomy and intraoperative photography, though it may wash out color and skin tones. Standardized use of auto white balance without a flash in a compact camera is a close second. Macro-mode or close-up focusing may put sterility of the operative field at risk and is more problematic. Automatic exposure reliably creates an image with proper lighting in the operating room.

The need for proper composition of the picture remains in the operative setting or emergency department and may be overlooked amidst other priorities. The framing principles already discussed should be followed to the extent allowed by the sterile field and drapes. Anatomic landmarks should be included at the borders of the frame. Shiny instruments, stained surgical drapes, gauze or glare from overhead lights must be eliminated or covered. Often the overhead lighting is harsh and must be removed from the field to prevent oversaturation of the image.

Archiving and image management

Cameras

There are many excellent resources in the literature for discussions on film photography. The era of light sensitive silver halides suspended in a gelatinous emulsion in film photography resides in niche markets, essentially outside the field of plastic surgery.¹⁶ Film or analog photography had an amazing 160-year run from the 1840s, before being supplanted by digital, around the new millennium.¹⁷ Because the overwhelming majority of cameras in use today are digital, we will concentrate here on digital. Like a film, digital imagers generally consist of red, green, and blue filters. Film has continuous stacked emulsions or layered films of colors, while digital uses variations on a checkerboard pattern of cells to filter light. In the Bayer pattern, most commonly found in digital cameras, every other pixel is green, while one in four is either red or blue. A few cameras, like those from Canon, use a complementary metal oxide semiconductor (CMOS) sensor, but most use charged couple devices (CCDs). In the former, each element contains its own transistor and circuitry providing for independent reading of data. When photons strike a CCD, charges propagate down each row of the checkerboard pattern and this limits the speed with which they can propagate. Newer CCDs have triple-stacked sensors (red, green, and blue, RGB) that lower resolution, but increase sensitivity.

Fig. 7.10 (A–G) Hands: standard views.

Well-designed cameras of either type will capture excellent images.

Choosing a digital camera can be overwhelming due to the myriad of choices available. Even a simple point and shoot can take excellent photos due to unrelenting commercial competition among manufacturers and the decreasing cost of

components. However, the plastic surgeon will require something more capable, albeit a large format, 35 mm size digital camera is not truly essential for adequate pre- and postoperative photographs in the proper setting. Mobile phone cameras are inadequate, as are entry-level compact devices. Lifestyle and fashion cameras are not suitable.

There were “resolution wars” in marketing cameras 10 years ago, but gladly those are over. Resolution is most often used to describe how many pixels are in the array. Minimum sizes now are $>3000 \times 2000$ or 6 megapixels. Actually, most cameras are capable of ≥ 16 . The number of pixels sets the upper limit of image quality, but not the lower limit. Another more important gauge of resolution is how sharply an image resolves fine detail, often depicted by extremely small, narrow lines. This is a more functional definition, though less commonly used.

The enthusiast compact category is generally adequate for plastic surgeons to use on a daily basis, if the additional expense of a prosumer or professional digital camera is not within the budget. Numerous features are available: high pixel count, large sensor size, an advanced hardware algorithm for interpreting the light image that strikes the chips, zoom and video capability are highly valued. Perhaps most important is the quality of the glass and the design of the optics in the lens itself. Features such as rapid shutter speed, geotagging, or very large aperture are not so critical in the patient-care setting. However, enthusiast cameras are capable of capturing images almost indistinguishable from higher end models in a controlled setting such as the plastic surgeon’s photography studio or the operating theater. Prosumer cameras have many of the features of a digital single lens reflex (DSLR). In essence, a plastic surgeon only requires a 50 mm equivalent and a 100 mm equivalent lens setting. Advanced computer design of camera zoom lenses has allowed for excellent shooting characteristics with compact cameras in both the 50 and 100 mm range, with minimal degradation of image quality. In other words, it is possible to get along with an enthusiast or prosumer camera in most situations.

Professional DSLRs are larger, heavier, machined to precise specifications, resistant to moisture and impact and sturdy, with full-frame 36×24 mm sensors that can potentially capture up to 25 megapixels in one image. Medium format cameras with pixel counts up to 60 million are rarely found or required in our specialty. The mirrorless interchangeable-lens camera is a newer class of digital system cameras that is gaining popularity. While they do not have a mirror reflex optical viewfinder, these cameras have been manufactured with various sensor sizes up to full-frame. Compared to DSLRs, mirrorless cameras are smaller and sturdier, while maintaining the versatility of interchangeable lenses. Almost all enthusiast cameras allow for high-definition video recording of several minutes duration. This is entirely adequate for documenting repeated key steps in an operative procedure, while not reaching the standards of a professional cinematographer.

Format

Storage

Digital memory cards come in a variety of types including compact flash and secure digital (SD). They are capable of transferring data at up to 30MB/s for high resolution video such as full HD or 4K video. HD resolution may be 720p based on vertical dimension (1280 pixels wide by 720 pixels high) or 1080i/1080p (1920 by 1080 pixels), with horizontal lines scanned interlaced (i) or progressively (p). 4K resolution

refers to a display device or content having horizontal resolution on the order of 4000 pixels. Under the previous convention, 4K would be equivalent to 2160p.

Secure digital media come in a regular or high capacity format (SD, SDHC, or SDXC). Recently, 128 GB and even 512 GB models are available worldwide with speed adequate to capture video at high resolution. Micro-SD cards are generally relegated to mobile phone cameras and data storage.

Memory card readers are widely available and inexpensive, like memory cards. Data can be uploaded to a computer via USB cable attached to the camera from the computer. However, it is quite common to remove the card, insert a spare into the camera and read the data from a card reader.

With the advent of the multi-terabyte hard drive, both desktop and portable, storage of thousands or tens of thousands of pictures is no longer an issue. Maintaining a disciplined, regular back-up program, however, is as essential as any record-keeping in the practice. At least two copies should be maintained onsite, and another offsite at a remote location to obviate water, fire, or earthquake damage.

File formats

There are dozens of data structures or architecture, also known as file formats. We will only concentrate on a few of the most commonly used: TIFF, JPG (or JPEG, for joint photographic experts group), Photoshop, GIF and RAW. Fortunately, almost any software will convert one still image type to another. However, it is important to understand their advantages and disadvantages.

TIFF is best used for print reproduction because it is a bit-mapped (like a printer) or raster Tag Image File Format. It supports 24-bit color depth per pixel, dimensions and color look-up tables “tagged” to the header of the data file. The way the tag specification is written gives rise to various versions of a TIFF file. Lossless compression with the LZW algorithm makes compression safe for data quality.

JPEG (JPG) is perhaps the most common file type, and it is “lossy”. Compression can be chosen from a 12-part scale from none to as much as 90%, while data quality diminishes accordingly. For quick exchange of images via email, this is ideal. Minimal compression almost retains original image fidelity. There is almost no software that cannot easily read this format, and with wide latitude in software storage parameters there is great flexibility.

Photoshop (PSD) is a proprietary format of Adobe Systems Corporation (San Jose, CA), but is so commonly used as to almost be a standard. Color management, 48-bit color and layers are supported.

RAW format varies from camera to camera because it is dependent on the hardware interface with the light capturing chip (CCD or CMOS) inside the camera. These files are sometimes called digital negatives because they fulfill the same role as negatives in film photography. It is the truest image as there is no white balance, color processing, compression, sharpening, or other manipulation of the data. Because the data is unprocessed, capture rates can be much faster with higher throughput. RAW has numerous advantages over JPEG including higher image quality, finer control, non-destructive change capability, and lossless compression. However, camera RAW file size is typically 2–6 times larger than JPEG files, and

lack of standard RAW image format requires more specialized software to open RAW files.

Video, unfortunately, is plagued by numerous incompatible standards. Even file formats with identical suffixes may be unreadable by other software or hardware, e.g., MP3 or MP4 (motion picture experts group 3 or 4) are often not readable unless the original software used to create the file is available. A software codec (coder-decoder) is required and often not cross-platform for PC or Mac. That rigorous discussion awaits another setting.

Image attributes, metadata, and retrieval

As the images are safely transferred to storage media, critical new information must be attached to the data. Modern cameras use a format called EXIF for recording camera type, lens, date, time, shutter, aperture, and many other items. Even more critical for plastic surgery is information like patient age, sex and weight, ICD-10 diagnostic codes, CPT procedural codes, type of implant used, pre- or postoperative status, date of original surgery and other critical pieces of medical data. These are proprietary to individual software packages and make changing platforms difficult after even a few months or a year of use. What once was a demanding and difficult exercise is now made transparent and easy by improved software interface designs.

The Health Insurance Portability and Accountability Act of 1996 (PL 104-91) has resulted in a major increased emphasis on patient privacy among other concerns. The broad interpretation of this law includes any part of the medical record. The American Recovery and Reinvestment Act of 2009 extended Privacy and Security Provision of HIPAA to business associates of covered entities and provides for stiff civil and criminal penalties for violation. Loss or dissemination of digital images can be much more serious than film photographs, with the risk of electronic data “going viral” over the internet to millions of people.

Digital image processing

Measurement and analysis

Orthognathic surgery has rested on the principles of image measurement and analysis since the early days of film photography. Measurements were made directly on photographs or transparencies and taken to the operating room to guide surgical osteotomies. Now these measurements can be made directly on the digital image. A well-developed model of cleft lip repair has been incorporated into the training program for a large charitable organization prior to surgeons going overseas on mission work.

Identifying and highlighting anatomic landmarks for the medical record in breast augmentation surgery increasingly has become a part of the preoperative consultation.¹⁸ It is the first step in building a predictive model for planning pocket dissection, choosing implant size, evaluating postoperative size and may lead over time to reduced rates of re-operation.

Planning and simulation

The term surgical simulation has been broadly defined to include anything from computer-assisted tutorials to

interactive learning to engaging in mock surgery with haptic feedback and complete with unexpected complications.¹⁹ Surgical planning is more easily achievable, and requires less computer power and complexity in programming. Organized medicine was challenged by the Institute of Medicine Report, *To Err Is Human: Building a Safer Health System* in 2000.²⁰ It has been estimated that 44,000 deaths occur yearly due to medical errors, the seventh leading cause of death. Many of these occurred during surgery, as a result of surgical planning or postoperative care.

Computer-based virtual surgical planning (VSP) is generally available in plastic surgery from commercial companies (Nex-Tech, Stryker, Canfield, and CrisaliX). Standardization of patient topographical measurements can be utilized to enhance preoperative planning and improve postoperative outcomes. More elaborate mannequin-based systems are becoming more mainstream due to the advent of 3D printing. Customized implants and prostheses have been used throughout plastic surgery, and the integration of precise anatomical topography in the preoperative setting with 3D printing could revolutionize the world of implants in plastic surgery.

New frontiers

Three-dimensional surface imaging

In conventional medical procedures, diagnosis, treatment, and outcome are typically judged by objective criteria. The patient's subjective feelings are of relevance, but of a secondary nature. In plastic surgery, on the other hand, the healthcare model is often one of wellness and enhancement, the patient is not ill or diseased and therefore the diagnosis, treatment, and outcome may be dominated by the patient's subjective assessment of an elective surgical procedure. Consequently, even the most technically perfect surgical procedure can lead to patient dissatisfaction, should the result not meet aesthetic and psychological expectations. Failure to meet these expectations can lead to the need for re-operation, increased medico-legal risk and additional costs directly to the surgeon. Furthermore, the market dynamics of cosmetic surgery are strongly driven by patient referrals, which again are based upon patient satisfaction. In breast augmentation surgery, for example, it can be advantageous that the patient is collaboratively involved in the process of implant selection, supported by the surgical team, and that the patient ‘buys in’ to the selection process with enthusiasm, confidence and conviction. One of the major reasons to undergo plastic surgery is to change the external appearance of the patient; a central question that all patients have in common is “how should I look after my operation?” One way to answer this is through 3D imaging.²¹

Today, 3D physics-based finite element analysis (FEA) technology can provide patients with a simulated view of their anatomy in a postoperative condition. While there are other methods to show the patient a probable outcome – such as special bras and sizers, computer slide shows with various before/after photographs of previous patients, collecting photographs from magazines, and morphing software based on photographs – all have limitations. All these methods require realistic imagination by the patient. State of the art technology allows patients to see themselves from varying

angles in 3D before the operation, increasing communication with the surgeon by interacting collaboratively with the image, and simulating the outcome of the surgical procedure.

Techniques for 3D modeling include, on one hand, expensive, space-limited and obsolescence-sensitive hardware scanners, and on the other hand, those based on the physical reconstruction of the body from 2D photographs. The former requires a large upfront investment amortized over time. The latter method functions on a pay-as-you-go basis and takes advantage of ease of use, simplicity, and minimal interference with the way the surgeon performs a consultation. When no special hardware is required, photographs are coupled with anatomical measures and physiologically-based data processing and simulation. Whatever technique employed, 3D and virtual reality are the future.^{22–26}

Video

Much of what has been said of 3D technology can be said of video medical records, other than the simulation aspects. Motion picture film has been a part of medicine for decades for surgical education, while digital video as a part of a medical record is a recent and evolving innovation, not yet standard of care. Almost every modern digital camera has the capability of capturing video clips. However, the lenses are not specifically designed for professional quality where heavy, expensive equipment is required and more computer power and capability is mandatory. Creation and routine use of detailed video is beyond the scope of most busy plastic surgery practices, though it provides a method to augment surgical education and analyze personal operative

performance. It obligates a commitment to production values, editing, composition, and a host of skills residing in the professional medical videographer. Short videos can document features such as range of motion, bulk strength and tone, elasticity and even aesthetic contours in motion. However, long compositions require expert direction, videography and editing. One potentially cost-effective solution is the use of commercially available amateur point-of-view video systems in the operating room. The future will certainly increasingly incorporate digital video in the practice of plastic surgery.²⁷

Presentations

In the era of digital media, the art of medical presentation should be mastered by every plastic surgeon to educate patients, students of surgery, and other healthcare providers. The nature of our specialty encourages photography and videography to take center stage in a digital slideshow.

Key principles

- When creating slides, think big font and limited text.
- Cite examples and use case presentations.
- Utilize appropriate animations to illustrate techniques and concepts.
- Use emphatic and descriptive gestures during live presentation.
- Ask effective questions to engage the audience.

Patient safety in plastic surgery

Bruce Halperin[†]

SYNOPSIS

- Modern medicine has greatly reduced the risk of surgery.
- Identifying which patients are at greatest risk for surgery starts the risk reduction process.
- Identification of medical factors leading to complications helps prevent untoward outcomes.
- Specialized care for the liposuction patient.
- Specialized care for the patient having facial aesthetic surgery.
- Avoiding fire in the operating room.
- Protocol-based systems for risk reduction.
- Reducing patient risk through optimal patient care.
- Do it better, do it safer.

The risk of having surgery

The decision to perform surgery to correct a defect or medical condition begins a cascade of decision-making and, by necessity, a series of compromises. It is the underlying desire of the medical profession to prolong and enhance the lives of patients who seek attention. Since the beginning of the practice of medicine it has been understood that undesired outcomes may occur. The acceptance by the patient of undesired outcome has changed over the course of medical history. As medical science has progressed, the expectations of patients and the medical profession have risen. As medical science understands ever-increasing levels of human biologic complexity, the expected outcome from medical intervention may change yet again. It is not yet clear to the practicing physician or public as to the fundamental cause of undesired medical outcomes.

It is clear that many of the undesired outcomes we now see are a result of failure to implement knowledge we already possess. We must further question whether it is our healthcare

delivery system that is in fact responsible for many of the undesired outcomes that our patients face. When we decide to perform a surgical procedure we accept the risk of undesired outcome. Using the knowledge gained from scientific studies, we select what we believe to be the “best” path to resolution of the patient’s condition. The question in our minds must always be: What is the “best” pathway in this particular surgical case?

Prior to the introduction of anesthesia the surgical experience was a decidedly unpleasant one for the patient. The success of a surgical procedure (read: survival) was often based on the speed at which the procedure was accomplished. If nothing else, the introduction of anesthetic techniques brought the ability of the surgical team to take more time in accomplishing the procedure. The introduction of an additional medical intervention (anesthesia) on the patient brought additional undesired effects and perioperative death.^{1,2} Since the introduction of general and regional anesthesia as part of normal surgical practice, surgical and anesthetic complication rates have been analyzed using a variety of clinical criteria. It is this wide variety of criteria that has led to confusion in the medical literature and in the mind of practicing clinicians of the actual risk attributable to anesthesia care during a surgical intervention. Do we consider in our complication rate only events that happened during the actual surgical procedure? Do we only consider events attributed solely to providing anesthesia or do we consider the contribution of surgery to the untoward outcome?³ The time course for evaluation of surgical and anesthetic complications remains controversial and almost certainly is related to the nature of the surgical procedure and type of anesthesia, if any, that was used during surgery. The wide variety of time indices that are used in the medical literature for the study of perioperative complications makes comparison of studies very difficult. Definitions of the time period for study of perioperative mortality range from 48 hours, as defined by the Joint Commission on Accreditation of Healthcare Organizations, to 30 days, as defined by the American College of Surgeons. Similarly, the inability to compare clinical studies adds to the confusion in defining

[†]Deceased

Table 8.1 ASA classification

ASA I	Normal healthy patient without active disease
ASA II	Patient with mild systemic disease (e.g., hypertension under medical control)
ASA III	Patient with severe systemic disease
ASA IV	Patient with severe systemic disease that is a constant threat to life
ASA V	Patient who is moribund and is not expected to survive without surgery
ASA VI	Patient who has been declared brain-dead for organ donation
ASA, American Society of Anesthesiologists.	

clinical risk to the patient from a given surgical or anesthetic technique. For anesthetic risk we need to consider not only cases where anesthesia is deemed the sole cause of complication and mortality but also cases where anesthesia is a significant contributing factor of complications and mortality.

It remains extremely difficult, even with review of the extensive body of medical literature, to predict accurately the risk for any given patient who is about to undergo any given surgical procedure. We can confidently claim that complications from anesthesia have been greatly reduced since the widespread acceptance of modern anesthetic techniques. Beecher and Todd published in 1954 that, where anesthesia was a very important contributing factor, death occurred in 1:1560 surgeries.⁴ Today, patients want to know the current state of the art of medical science in regard to perioperative risk and complication. One of the most useful and popular ways to assess risk in the surgical patient population is by the American Society of Anesthesiologists (ASA) physical status. This classification system was originally designed in the early 1940s and updated in 1961 (Table 8.1).

The ASA classification system has been shown to correlate with surgical and anesthetic outcome.⁵ Lagasse's study⁵ concluded that the incidence of anesthesia-related mortality within 48 hours of surgery was 1:13000 procedures, when evaluating all patients coming for a surgical procedure. Of great interest, but of little surprise to the practicing anesthesiologist, was that anesthesia-related deaths increased with increasing ASA classification. Other reports dating as far back as 1987 report anesthesia-related mortality rates at 1:185000.⁶ The study by Buck *et al.*⁶ was performed before the widespread acceptance of new technology monitoring systems (pulse oximetry and capnography) that serve as early-warning systems for respiratory compromise. More recent studies have shown even better safety outcome results for patients having surgery. A 2004 study performed in France again showed that mortality rates increased with increasing patient ASA status,

at a rate of 4 deaths per million surgeries for ASA category I patients and with 554 deaths per million in ASA category IV patients.⁷ The effect of medical progress on improved clinical outcome is often difficult to detect when the incidence of maloccurrence is infrequent. Significant changes in daily anesthesia practice began in the mid-1980s with the introduction of the Harvard Standards of Practice I – minimal monitoring. These anesthesia standards required the use of monitoring devices to detect and prevent impending disaster during surgery.⁸ The 1986 ASA standards for basic intraoperative monitoring encourage both capnography and pulse oximetry during conduct of anesthesia and surgery. The incidence of accident and death rate in ASA status I and II patients was studied before and after the adoption of the new monitoring standards at Harvard hospitals (Table 8.2). The implementation of these standards, along with the introduction of new monitoring techniques, has greatly reduced the incidence of unrecognized hypoventilation and hypoxemia leading to intraoperative complication and death.⁹⁻¹¹

The implications of these findings for current clinical practice in the operating room are clear. Monitoring equipment for electrocardiogram, blood pressure, pulse oximetry, capnography, inspired concentration of oxygen on anesthesia machines, and temperature must be available in the operating room, functioning and used in all appropriate situations. The proper use of monitoring devices during surgery improves safety during surgery. Nonfunctioning monitoring equipment postpones surgery.

It is the experience gained from in-hospital surgery and advances in medical care that have allowed the development of outpatient surgery. Recent data show that upwards of 60% of surgery at community hospitals in 2005 was performed in an outpatient setting.¹² It is almost certain the percentage of patients undergoing cosmetic and reconstructive surgery on an outpatient basis is even higher. In the mid-1970s there were two free-standing outpatient surgery centers in the US. There are now over 5000. The success of outpatient surgery done outside a hospital operating room is based on the cost-efficient ability of these centers to meet the medical needs of the patient and the medical staff safely. It has been shown repeatedly that outpatient surgery can be performed with a safety standard equal to or exceeding that available in an inpatient hospital-based environment. The spectrum of settings for performance of surgery continues to expand with the development of office-based surgical facilities.¹³ The American Society of Plastic Surgery through the Patient Safety committee has published an outstanding series of articles outlining advisory principles for safety in ambulatory surgery.¹⁴ These reports, based on the medical literature combined with the general principles described above, set an educated guideline for conduct of outpatient plastic surgery. A primary area of concern for the plastic surgeon is patient selection for surgery

Table 8.2 Incidence of intraoperative anesthesia complications

Dates	ASA status I and II patients (n)	Intraoperative accidents (n)/incidence		Death (n)/incidence	
1/1976–6/1985	757000	10	1/75700	5	1/151400
7/1985–6/1988	244000	1	1/244000	0	0/244000
Monitoring standards instituted 7/1985. ASA, American Society of Anesthesiologists.					

and whether or not to perform the surgery on an outpatient basis. We have previously described the data that demonstrate that complications increase with an increase in a patient's ASA status. Prospective stratification of 17 638 patients by age found that patients over the age of 65 years were 1.4 times as likely to have an untoward intraoperative event and twice as likely to experience an intraoperative cardiovascular event as patients under 65.¹⁵

Obese patients/sleep apnea patients having plastic surgery

Multiple studies have demonstrated an increase in perioperative risk associated with obesity. Complications during surgery associated with patient obesity include increased rates of failed regional anesthesia, unplanned hospital admissions, and an increased incidence of deep venous thrombosis.¹⁶ It is also unreasonable to expect medical care providers to be able to manage the obese patient physically without assistance from other healthcare assistants. Unless an ambulatory center is prepared to have the help the obese patient will require, the patient should have surgery in a facility with the necessary staff available. Setting a weight limit for patients, based on the ability of the staff of the center to manage the patient, avoids uncomfortable situations when the patient arrives for surgery and the facility is unable to take care of him or her. Proper planning at the surgical facility reduces surgical cancellations. Obese patients have a higher incidence of sleep apnea than patients of normal body habitus. Physical characteristics that predispose patients to having obstructive sleep apnea include body mass index over 35, neck circumference of 17 inches (43 cm) in men or 16 inches (41 cm) in women, craniofacial abnormalities affecting the airway, nasal obstruction, and tonsil hypertrophy.¹⁷

The 2006 report by the ASA taskforce on perioperative management of patients with obstructive sleep apnea is a valuable reference for conduct of care of this classification of patients.¹⁷ The severity of sleep apnea, as determined by a formal sleep study, is seen in Table 8.3. The severity of oxygen saturation depression during apnea events and the number of apneic events per hour should be considered in evaluating the patient for surgery.

Proper perioperative clinical management of patients with sleep apnea is of critical importance. Airway management of the obese patient, with or without sleep apnea, may be difficult. Careful airway evaluation preoperatively with notation of mouth opening, mental-hyoid distance, submandibular compliance, range of motion of the cervical spine, and

Mallampati score may indicate potential difficulties in airway maintenance and intubation.¹⁸ Conduct of the actual anesthetic for patients with a history of sleep apnea and having plastic surgery depends on many factors. Certainly the type of surgery, the severity of airway disease, and the desires of the patient are major components in the decision-making process. The need for intubation or airway manipulation during surgery should not be an automatic exclusionary criterion for outpatient surgery in a patient with a history of sleep apnea. Appropriately selected patients with a history of sleep apnea who are observed and monitored for extended periods of time after surgery may do well on an outpatient basis. Patients with sleep apnea requiring large amounts of postoperative narcotics or sedatives and those who are noted to have decreased oxygen saturation levels on room air or inadequate ventilation will require admission and continued monitoring in an acute care setting. Monitoring of the sleep apnea patient after surgery and after hospital admission includes continuous oxygen saturation. Monitoring of oxygen saturation levels on an every 4–6-hour basis makes no sense given the fact that obstructive apneic events are more likely after surgery and hypoxic brain injury may occur in a matter of minutes.

In addition, it may be unwise to attempt to complete a surgical procedure on a patient with sleep apnea using local anesthesia with deep levels of sedation. Commonly used medications for sedation during surgery, including narcotics and benzodiazepines, may exacerbate apneic episodes leading to hypoxia and hypoventilation. Performing procedures on a patient with sleep apnea with the patient in the prone position and limited airway access without first securing the airway may be particularly hazardous. It is often difficult to monitor ventilation accurately in a nonintubated patient. New technologies to detect hypoventilation will need to be developed to monitor ventilation accurately in nonairway-controlled patients. Development of continuous arterial CO₂ monitoring using a noninvasive format will further improve patient safety during surgery.¹⁹ Patients using continuous positive airway pressure (CPAP) as a therapeutic modality for sleep apnea should be instructed to bring the CPAP equipment to the surgical center. The center should have personnel knowledgeable in the application of CPAP devices available to assist in the respiratory care of the patient. Similarly, patients who use CPAP at home should use their CPAP while resting or asleep at the hospital.

Despite careful attention to airway evaluation, clinical experience and prospective studies have demonstrated a relatively poor ability of the medical practitioner to predict which patients will have a difficult airway. Upwards of 3% of patients deemed to have “normal” airways may have difficulty with intubation. The implications of our inability to predict which patients will have a difficult airway include the need to have an extensive selection of airway management tools available in the surgical setting where airway complications may arise. In addition to the traditional array of laryngoscopes and blades, airways, and endotracheal tubes of many sizes comes the need for fiberoptic laryngoscopes, laryngeal mask airways, and the personnel who can readily use these tools. Newer technologies, including video laryngoscopes, should be available to those trained in these techniques. It is not a question of how much equipment you can purchase, but which equipment you are skilled at using during an emergency to establish an airway. Every surgical facility should

Table 8.3 Criteria for determining the severity of sleep apnea after sleep study

Severity of obstructive sleep apnea	Adult apnea–hypopnea index	Pediatric apnea–hypopnea index
None	0–5	0
Mild	6–20	1–5
Moderate	21–40	6–10
Severe	>40	>10

be capable of performing a surgical airway (tracheostomy) in the rare case of failed airway management.

Review of large databases evaluating the safety of surgery has shown that surgery and anesthesia are very safe. The risk of anesthesia as the cause of death in ASA I and ASA II category patients is in the range of 1:150 000–1:300 000 patients.^{20,21} Therefore, it should be no surprise when medical publications are presented with a small series of patients undergoing outpatient surgery in an office-based surgery center that the reported complication and death rates are very low.²² In a study on office-based surgery, 84.3% of patients were ASA class I, 15.6% ASA II, and only 0.1% ASA class III. It would require a very large data collection of ASA I and II patients to provide evidence of increased risk or an improved outcome in a particular surgical setting or using a specific anesthesia technique in this subset of patients.

Similar publications have documented the highest levels of safety in the office surgery environment using general anesthesia. Hoeflin *et al.* published a series of 23 000 consecutive surgical patients over an 18-year period. The advantages of general anesthesia with airway control during surgery are also presented.²³ Again, given the relatively low incidence of complications in this patient population and the small number of patients studied, it will be difficult to show statistically significant change in clinical complication rates. The American Association for Accreditation of Ambulatory Surgery Facilities study of 400 675 patients concluded that patient safety in accredited office-based surgical facilities was equal to or exceeded the safety level of surgery in a hospital.²⁴ As these articles propose, there are tangible benefits to office-based surgery, including cost containment, convenience, and ease of scheduling. There is little doubt that patients prefer the quieter, gentler ambience of the office/outpatient surgery center as compared to a busy hospital environment. The office-based surgery/outpatient surgical environment can provide a superb surgical environment for patient, physician, and staff as long as the quality of care equals or exceeds that of the full service hospital in all regards.

Intraoperative management of the plastic surgery patient

Both the medical literature and nonpeer-reviewed publications extol the virtues of a variety of anesthesia techniques for plastic surgery, in particular aesthetic surgery. The general public would like to believe that a less invasive and seemingly simpler anesthesia technique will be safer. Physicians who are not knowledgeable of the medical literature may contribute to this misconception. As we have seen in the case of patients with sleep apnea, local anesthesia with deep levels of sedation may not be an appropriate anesthetic choice and may put the patient at substantial risk of airway compromise. Both local anesthesia and general anesthesia produce a similar incidence of complications in patients having oral surgery on an outpatient basis.^{25,26} The 2006 closed claims analysis from the ASA Closed Claims database demonstrated that, relative to the incidence of the anesthesia technique, death during monitored anesthesia care and general anesthesia was twice as common as in patients undergoing a regional anesthetic.²⁷ The primary complication leading to death in this study was inadequate

oxygenation and ventilation. In this closed claim study, respiratory insufficiency was found to have occurred in 15% of patients who had monitored anesthesia care versus 7% of patients who had general anesthesia. Other factors in this group, such as patient age and ASA classification, may have contributed to the findings. Randomized studies comparing anesthesia technique for a given surgical procedure must be performed before declaring a winner in the category of anesthesia technique for patient safety. Very large patient populations will need to be evaluated so that appropriate conclusions can be drawn.

Some anesthesia techniques used during surgery appear to have been poorly evaluated for possible complications. Epidural anesthesia for patients undergoing liposuction appears to expose the patient to large doses of local anesthetics when used in both the delivery of epidural anesthesia and as a component of the tumescent solution. Vasodilation by regional anesthetic blockade of the sympathetic nervous system seems to conflict with the application of dilute solutions of epinephrine for vasoconstriction during liposuction. Again, heavy sedation of a patient in the prone position with a high dermatome level of regional anesthetic seems unwise for patients undergoing liposuction because of concerns with airway compromise and respiratory insufficiency. Despite these considerations, numerous publications have supported regional anesthesia use in this setting. A well-thought-out anesthetic plan that is coordinated with the surgeon and operating room staff will add to patient safety.

Advances in medical technology and medical practice have allowed the development of outpatient surgery to be performed in both a free-standing surgical center and in the medical office-based surgery setting. The American Society of Plastic Surgery commissioned a taskforce on patient safety in office-based surgical facilities and published a taskforce statement.²⁸ This taskforce statement provides conservative judgments on the nature of surgical procedures appropriate for the office-based setting and the appropriate magnitude of these same surgeries. Of particular interest to the practicing physician was the recommendation for limiting the volume of liposuction to a total of 5000 cc of total aspirate volume (fat and fluid). A large study looking at the clinical outcome of 631 large-volume liposuction patients showed a high degree of safety and extremely low complication rates with much larger total aspirate volumes.²⁹ Our current clinical policy limits aspirate volume to 5000 cc of supernatant fat in the outpatient setting and allows aspiration of an additional 1000 cc of fat for patients admitted to the hospital after surgery for continued monitoring. The medical literature provides very little basis for the taskforce recommendations and the medical literature and clinical experience suggest that larger aspirate volumes may be safely performed at a single operation. The physiologic injury of liposuction depends on the surgical technique employed and the body surface area of the patient. Removing 5000 cc of fat from a 100-lb (45-kg) patient will have very different physiologic consequences than the same type of surgery performed on a much larger patient.

Recommendations for limits on liposuction aspiration should be based on appropriate medical and physiologic considerations. Suggestions have been made to limit the duration of a plastic surgery procedure as a method of establishing safe medical practice. Perioperative clinical risk increases

with longer surgical duration. Bringing the patient back to the operating room for a second surgery also involves exposing the patient to additional risk. The decision to perform one longer surgery or two shorter surgeries involves many factors.

The American Society of Plastic Surgery Patient Safety Committee published *Evidence-Based Patient Safety Advisory: Liposuction* in 2009.¹⁴ The use of lidocaine as a component of the wetting solution injected into the fat prior to aspiration has been well discussed in the medical literature. Local anesthetic in the wetting solution is used for two purposes. The first is to reduce the level of additional anesthesia (general or sedation) that is needed to complete the procedure and keep the patient comfortable during surgery. The second purpose is to provide postsurgical analgesia in the body areas where surgery has been performed. Death from local anesthetic overdose has occurred during liposuction. Mistakes have been made in the compounding of the wetting solution used during liposuction surgery. Bottles of 2% lidocaine have been added to the wetting solution when 1% lidocaine was prescribed for compounding. Bupivacaine 0.5% has been added to wetting solutions when lidocaine 0.5% was prescribed for compounding. Catastrophic outcomes have occurred from these errors. The compounding of wetting solutions must be confirmed by two individuals to ensure accuracy and prevent error. Limitation of lidocaine dosing must be conservative because of erratic and unpredictable serum levels of local anesthesia from any given wetting solution administration.^{30,31} Multiple studies have documented that plasma lidocaine levels peak 10–12 hours after wetting solution containing dilute concentrations of epinephrine is injected in the adipose tissue prior to liposuction. For patients undergoing liposuction on an outpatient basis, peak lidocaine levels will occur after discharge from the surgical facility. Following tumescent injection into highly vascular areas of the body such as the neck, peak lidocaine levels occur more rapidly (6 hours) and at higher serum levels.³² In liposuction surgery with large volumes of tumescent injection, sources of additional local anesthetic administration, such as laryngeal tracheal anesthetics, should be avoided by the anesthetic provider. Epinephrine levels peak after tumescent injection at about 3 hours postinjection.³⁰ It has been postulated that elevated epinephrine levels post tumescent injection may contribute to renal blood flow changes, leading to decreased urine output during larger-volume liposuction.²⁹ Perioperative fluid management for the patient undergoing liposuction has been a topic of great debate. Clinical studies and clinical experience have shown that approximately 30% of injected wetting solution is aspirated during liposuction with 70% of the injected tumescent volume remaining in the adipose tissue and subsequently absorbed into the central circulation.^{33,34}

Deep venous thrombosis/pulmonary emboli in the liposuction patient

Risk stratification and institution of appropriate therapy for prevention of venous thrombosis and pulmonary embolism is a key component of perioperative medical management. Preoperative medical evaluation of patients with a history

of coagulopathic disease, venous thrombosis or pulmonary embolism will aid in developing appropriate perioperative strategy for reducing the risk of thrombotic events during and after surgery.³⁵ The use of prophylactic therapy for prevention of venous thromboembolism during surgery has been well established in the medical literature.³⁶ However, determining an appropriate therapeutic program for venous thromboembolism prevention remains confusing for many surgical practitioners, especially when the surgical procedure is deemed “minor”, the duration of surgery is deemed short, and the patient is discharged home after recovery from surgery and anesthesia.

Nonpharmacologic therapy (compressive hose and intermittent pneumatic compression of the foot/leg) may reduce the risk of deep venous thrombosis (DVT) by up to 60%.³⁵ Pharmacologic therapies for prevention of perioperative DVT has been shown to be more effective than mechanical therapies alone but increases the risk of major bleeding complications from surgery. The use of both mechanical and pharmacologic therapy for prevention of perioperative DVT has not been shown to add additional protective benefit over pharmacologic therapy alone.³⁵ Combined use of both compressive hose and pneumatic compressive devices has not been shown to reduce the incidence of DVT over compressive devices used alone. Elastic stockings causing skin complications in some patients are of concern. The duration of use of pharmacologic therapy for the prevention of DVT will be based on specific patient needs. The use of an inferior vena-caval filter as a *primary* prophylaxis modality is generally not recommended but may be appropriate for patients having a pulmonary embolism in the postoperative period. The primary concern with chemoprophylaxis for venous thromboembolism prevention is postoperative bleeding, particularly after facial cosmetic surgery, surgery that may affect patency of the airway, and liposuction where large areas of tissue have been disrupted and blood collection may be extensive. As a result of these concerns, prophylactic therapy for ambulatory plastic surgery has focused on the use of graduated compression stockings (compressive hose) and the use of intermittent pneumatic compression devices fitted for the foot/leg. The use of these techniques has been shown to reduce the incidence of venous thromboembolism.³⁷ It remains to be demonstrated whether these nonpharmacologic techniques prevent pulmonary embolism or death following outpatient plastic surgery. Compressive hose must be properly fitted for them to be effective, and ill-fitted stockings may lead to venous occlusion or arterial compromise of the lower extremity.

The use of intermittent pneumatic compressive devices for the leg or foot increases venous flow and is thought to reduce pooling of blood in the veins. Once again, proper fitting of the device is mandatory and use of the pneumatic compressive device should start before beginning anesthesia and continue through the recovery period in the postanesthesia care unit. The development of venous thromboembolism may extend well into the postoperative period following discharge from the medical care facility. In selected cases it may be wise to continue mechanical prophylaxis at home, after discharge from surgery, for the high-risk patient. Patients who have undergone circumferential liposuction of the thigh or calf, where the venous flow of the lower extremity may be compromised, may benefit from extending the duration of mechanical

prophylaxis. Mechanical prophylaxis is contraindicated in patients with lower-extremity edema, a history of peripheral vascular disease of the lower extremity, or wounds or ulcers of the feet or legs.

Patients at high risk for venous thromboembolism include those with a history of prior venous disease, obesity (body mass index >30), postoperative immobility, diabetes, history of tobacco use, history of cancer, advanced age, long duration of surgery, and the use of general anesthesia.³⁸ This subset of high-risk patients may benefit from a combination of mechanical and pharmacologic prophylactic measures to reduce the incidence of venous thromboembolism. Patients who are thought to be hypercoagulable (e.g., protein S deficiency or factor V Leiden) may also warrant both mechanical and pharmacologic therapy for thromboprophylaxis during outpatient ambulatory surgery.³⁹ Pharmacologic prophylaxis is contraindicated in patients with active bleeding, recent or anticipated regional anesthesia (epidural or spinal), infective endocarditis, proliferative retinopathy, and in patients with thrombocytopenia. Patients undergoing surgery with epidural anesthetics and the use of an indwelling epidural catheter should have the catheter removed before starting anticoagulant therapy. In patients with an indwelling catheter in whom anticoagulation therapy has been instituted, the catheter should be removed at the low point of clinical effectiveness of anticoagulation therapy; that is, just before the administration of the next dose of medication. The international normalized ratio should be <1.5 at the time of catheter removal. The use of heparin and low-molecular-weight heparin is contraindicated in patients with a history of heparin-induced thrombocytopenia. Fondaparinux may be an appropriate prophylactic therapy for patients with heparin-induced thrombocytopenia. Aspirin as a sole modality for venous thrombosis prophylaxis is generally not recommended. Aspirin may be indicated in a small subset of patients at high risk for venous thrombosis and with specific contraindications for other mechanical and pharmacologic therapies.

Intermittent pneumatic compression devices are routinely used for all liposuction patients because of concern with venous stasis, vascular endothelial injury, and/or activation of the coagulation pathway secondary to tissue trauma during surgery. Anticoagulation therapies started prior to or immediately following liposuction surgery pose substantial bleeding risk to the patient. During liposuction, large areas of tissue are disrupted during surgery and visualization of bleeding sites may be difficult. Patients who develop pulmonary thromboemboli in the early postoperative period and given aggressive anticoagulant therapy have experienced a great amount of bleeding in the body areas having liposuction. Anticoagulated liposuction patients will experience severe bleeding, even with aggressive compressive garment therapy in the regions of recent surgery. Vena-caval filters have been successfully placed in postliposuction patients experiencing pulmonary emboli. For postliposuction patients experiencing these life-threatening complications, consultation with critical care medicine and vascular surgery specialists is mandatory.

The development of a formal, institutional policy for prevention of DVT and thromboembolism is recommended. Compliance with institutional policy should also be monitored to ensure patients are receiving appropriate DVT prophylaxis therapy.

Care of the liposuction patient during surgery

Coordination of patient care during liposuction by the operating team is mandatory. Strategies for tumescent solution dosing, fluid management, patient positioning, and maintenance of the patient's body temperature during surgery should be planned prior to the start of the surgical procedure. Liposuction patients frequently have large portions of their body surface area exposed to cold operating room temperatures. Maintaining body temperature for the patient during surgery may become a complex problem for the surgical team. Anesthetics routinely cause blood flow redistribution, antagonizing the body's normal mechanisms for temperature regulation. Warmed intravenous fluids and tumescent solutions for liposuction will aid in temperature preservation. Water-based operating table heating pads have been shown to have little benefit for temperature preservation. Routine use of two forced air heating blankets, one over the upper part of the body and the second over the lower part of the body, have almost eliminated concern over hypothermia during liposuction. Changes in body positioning during liposuction surgery must be performed expeditiously, with reapplication of the forced air blankets as soon as is possible to maintain body temperature.

The most common postoperative complication after liposuction is skin and body contour irregularity. Of course, the most serious outcome after liposuction is death. Abdominal wall and vital organ perforation has been reported to occur in 14.6% of 95 fatalities following 496,245 liposuction procedures.⁴⁰ Patients with previous abdominal surgery or known to have a ventral hernia appear to be at increased risk of abdominal wall perforation. Careful preoperative abdominal examination will identify many patients with abdominal wall hernias. Advanced imaging by computed tomography scan may be necessary to help identify patients with abdominal wall defects that could lead to severe complications after abdominal liposuction. Meticulous surgical technique is required to reduce the incidence of vital organ injury. Perforation of the posterior flank, leading to retroperitoneal injury, thoracic perforation, and spinal cord injury, has been reported during liposuction. Delay in diagnosis of an abdominal wall perforation may lead to peritoneal spillage, necrotizing fasciitis, sepsis, and death.⁴¹ The only thing worse than such a catastrophic complication is the failure to diagnose such a condition. Physician denial that a complication has occurred is a strong component in the pathway leading to a devastating clinical outcome after surgery.

Complications during body contour surgery: fat transfer

The addition of fat transfer techniques has expanded the possibilities associated with body contour surgery. Prior to the development of fat transfer from one part of the body to another, body contour changes focused on fat removal (liposuction). The removal of fat from a donor source on the body combined with adipose cell processing and subsequent transfer to another part of the body has increased patient demand

for the procedure. With development of the transfer technique comes the possibility of intravascular injection of fat tissue and adipose cells leading to complications and death. Fat emboli as a complication of liposuction has been reported in the medical literature. Inadvertent intravascular injection of fat tissue has been reported during fat transfer to the buttocks.⁴² Microembolization of fat particles and large fat globules into the pulmonary vasculature has been reported. Fat transfer to the buttock may be performed by transfer of fat tissue to the subcutaneous/adipose region of the buttock or by transfer of fat tissue into the gluteal muscles of the buttock. Intramuscular transfer of fat tissue to the deeper muscular layers may increase the risk of intravascular injection to the deep venous plexus underneath the muscle layers. Inadvertent, deep intravascular injection into the iliac vessels has also been proposed as a mechanism for fat embolism to the lung. Determining the appropriate depth of tissue transfer to the buttocks may be difficult. Identifying the vascular structures deep within the buttocks with intraoperative ultrasound to avoid vascular injection has been proposed but remains an untested technique. Aspiration by syringe prior to injection of tissue may help avoid vascular injection of tissue but is unlikely to completely eliminate a potentially life-threatening complication. Deep needle penetration to the buttocks also raises the possibility of sciatic nerve injury when anatomical landmarks are distorted.

Embolization of tissue filler materials, including fat transfer, following injection into the face resulting in blindness has also been reported. It has been suggested that intravascular injection resulting in retrograde flow and embolization of the retinal artery is the cause of these unfortunate complications. Again, careful surgical technique may reduce the incidence of embolization. Careful aspiration prior to injection, and use of small-diameter, blunt-tipped needles may reduce the incidence of intravascular injection as compared to sharp, pointed tip needles.⁴³

Facial aesthetic surgery

Hematoma formation after facial rejuvenation surgery can have serious consequences. Small hematomas may be treated with conservative techniques, such as external pressure to the affected area, or require percutaneous aspiration with a needle and syringe. Large hematomas, expanding hematomas, or blood collections causing pressure on the patient's airway are more likely to require surgical intervention. Surgical studies have identified perioperative hypertension with systolic blood pressure greater than 150 mmHg and diastolic blood pressure greater than 90 mmHg as a prime marker for postoperative hematoma formation after facial surgery. Recommendations for aggressive blood pressure control surrounding the time of planned rhytidectomy have been proposed by many authors. Whether preoperative prescription of antihypertensive medications such as clonidine should be used to reduce the incidence of postoperative facial hematoma, as opposed to intraoperative titration of antihypertensive medications, is as yet unanswered. As with any such critical question, randomized studies will need to be performed. The administration of oral or intramuscular medications around the time of surgery should be carefully evaluated. The perioperative use of Thorazine® to control intraoperative and

postoperative blood pressure during rhytidectomy needs to be questioned. Thorazine® has a long half-life and a long clinical duration of action. It has numerous undesired drug interactions, including potentiation of narcotic analgesics, and a variety of side effects. Given that we now have better, titratable antihypertensive medications, more potent antiemetics, and better perioperative sedative medications, Thorazine® in the surgical setting is a drug best relegated to history.

Airway management of the patient with a postoperative facial hematoma may be frightening. Facial and neck hematomas may significantly distort the airway making direct laryngoscopy and intubation impossible. Careful evaluation of the patient's airway and anatomy distortion should be performed prior to administration of sedative medications or induction of general anesthesia in a patient with facial or neck hematoma. Deviation of the trachea by a neck hematoma or swelling of the base of the tongue or pharynx can cause airway obstruction. Traditional airway rescue techniques such as the laryngeal mask airway may not be effective because of anatomical distortions caused by the hematoma. Securing the airway with an endotracheal tube with the patient awake and spontaneously breathing may be the safest technique prior to induction of general anesthesia in patients with distorted anatomy from a postoperative hematoma. Opening a suture line with evacuation of a small area of hematoma may relieve pressure on the airway and restore a more normal airway anatomy. In this clinical setting, preparations should be made for performing a surgical airway prior to attempts at fiberoptic or awake intubation. Preparation for an airway crisis will help avoid a clinical disaster should airway complications develop. Massive neck swelling may also make performance of a surgical airway or cricoid thyroidotomy difficult.

Evacuation of a small postoperative facial hematoma after rhytidectomy may be an appropriate procedure for an office-based surgery center or free-standing surgery center. In a case with possible airway compromise following facial surgery, a hospital-based operating facility may provide the greatest level of safety for the patient. It may be necessary for the patient to remain intubated after hematoma evacuation because of continued swelling in the neck, pharynx, and base of tongue. Again, preparation for rapid deterioration of the patient's airway is mandatory.

Complications from breast surgery

The incidence of pneumothorax following breast augmentation and breast reconstructive surgery is very low – less than 1% of cases. The incidence of a pneumothorax following primary breast augmentation is fortunately very rare, but must be considered in a patient with otherwise unexplained postoperative respiratory complications. Pneumothorax after secondary breast surgery and breast reconstruction has been reported at a higher incidence but remains infrequent. Severe postoperative respiratory distress after breast surgery may require positive-pressure respiratory assistance and intubation along with needle aspiration of the chest for evacuation of a pneumothorax. Chest tube insertion for continued management of a pneumothorax is rare, but may be required for a persistent air leak. Keeping this potential complication in mind will allow recognition of the disorder when it presents itself clinically.

Fire in the operating room

The development of thermal injury secondary to a fire in the surgical field can lead to devastating consequences. As many as 200 operating room fires involving patients undergoing surgery may be occurring every year. The concept of the fire triad helps to explain the development of a fire during surgery. The fire triad comprises: (1) an oxidizer, which in an operating room setting includes oxygen and nitrous oxide; (2) an ignition source, which may be an electrocautery-type device or laser; and (3) a fuel source such as drapes, gauze, prepping solutions, or a patient's body tissue. Prevention of fires in the operating room during surgery starts with physician and staff awareness of the possible contributing factors to an operating room fire. The ASA Taskforce on Operating Room Fires has developed specific recommendations to reduce the incidence of operating room fires.⁴⁴ Oxygen-enriched environments readily promote ignition of a combustible material. The contour of the surgical drapes around the patient's face may allow oxygen to accumulate and promote combustion. Allowing free air flow around a surgical area may reduce the incidence of ignition of combustible material. Minimizing the delivery of supplemental oxygen (nasal cannula or face mask) to the surgical region may reduce the incidence of combustion. For patients receiving supplemental oxygen via nasal cannula or face mask while undergoing facial surgery, minimizing the oxygen concentration in the surgical field is mandatory. This may be achieved by using the lowest possible oxygen flow to the patient that produces satisfactory oxygen saturation levels, and by suctioning in the surgical field to reduce oxygen accumulation in the surgical area. It may be necessary to secure the airway for high concentration of oxygen delivery to the patient to reduce the risk of fire of the face or airway.

Surgical sponges should be moistened when used near an ignition source. Flammable skin-prepping solutions should be allowed to dry before draping to reduce the risk of accumulation of potentially flammable gases. The lowest possible cautery and laser settings should be used to limit ignition potential. Treatment of a facial or airway fire includes stopping the flow of delivered gases to the patient, removal of burning material as soon as possible, including an enflamed endotracheal tube if it has caught on fire, and extinguishing flames with saline as rapidly as possible. Concerns with airway thermal injury must be thoroughly evaluated with laryngoscopy and bronchoscopy if necessary. Airway management after facial fire or airway thermal injury will require additional medical consultation and intensive care unit monitoring of the patient.

Protocol-based systems for reducing wrong patient and wrong-sided surgery

Much of this chapter has discussed techniques for improving patient safety during surgery based on our knowledge of the pharmacology and physiology of the surgery being performed. Other portions of the chapter have sought to educate the medical practitioner through review of the medical literature of surgical and anesthetic risk. Other portions of this textbook seek to educate the medical practitioner on surgical

technique and improving clinical outcome through better surgery. Most physicians strive to improve clinical outcome by advancing their knowledge of the scientific literature that is the basis of medical practice. However, poor patient outcome during surgery is often due to failure of the medical system to meet the needs of the patient. Medical facilities should have mechanisms in place to ensure that patients receive the correct surgical procedure. Following this concept, the Joint Commission under the National Patient Safety Goals has adopted the Universal Protocol for Preventing Wrong Site, Wrong Procedure and Wrong Person Surgery.⁴⁵ The Universal Protocol is founded on the concept that performing the wrong surgery must be prevented and that aggressive strategies must be implemented for successfully protecting the patient. Verification of patient identity is performed multiple times by multiple individuals involved in the medical care and surgical care process. This verification process begins with preoperative patient verification and confirmation of medical conditions. This preoperative verification includes patient identity confirmed verbally with the patient and with checking the patient's arm band. Confirmation of the surgical site and surgical procedure along with proper surgical site marking by the physician or designee is performed. Verification of the surgical permit, appropriate history, and physical examination documentation along with laboratory studies and plans for blood transfusion are included in this preoperative review. Which members of the surgical team should be allowed to perform surgical site marking remains highly controversial in the medical community. These debates will continue, but it is safe to state that the surgical site must be marked preoperatively, meeting the National Patient Safety Goals and good perioperative medical judgment.

The World Health Organization has adopted a surgical patient safety checklist to reduce the incidence of medical errors.⁴⁶ This checklist includes procedures to be performed prior to the induction of anesthesia (Boxes 8.1 & 8.2).

Performance of the "time-out" procedure ensures that the correct patient is about to undergo the correct surgery on the correct surgical site. The "time-out" procedure requires that the entire operative team focus on the identification process and participate in performing the "time-out." The operative team includes the surgeon and surgical assistants, the anesthesia care provider, the nurse in the operating room, the surgical technician, and other individuals in the operating room who will be participating in the surgical procedure (i.e., radiology personnel). When more than one procedure is to

BOX 8.1 Confirm the following information with the patient prior to induction of anesthesia

- Patient identity
- Site marking by surgeon
- Surgical consent
- Current history and physical
- Allergy band
- Special needs or instrumentation, i.e., continuous positive airway pressure machine for after surgery for a patient with sleep apnea

BOX 8.2 Confirm with anesthesia care provider

Anesthesia safety check completed
 Pulse oximeter in place and functioning
 Anticipated difficult airway or pulmonary aspiration risk
 Risk of blood loss greater than 500 cc in an adult or greater than 7 mL/kg in a child
 Need for blood typing and crossmatch
 Special anesthesia equipment needs

be performed on the same patient by different surgeons, a “time-out” is performed before the start of each portion of the surgery. The “time-out” procedure must confirm:

1. The patient’s identity is correct.
2. The surgical site is correct.
3. The surgical procedure that is planned.
4. Surgical consent is complete and accurate.
5. The surgical site has been properly marked and is visible in the surgical field.
6. Imaging studies and implantable devices are available (if indicated).
7. Prophylactic antibiotics (if indicated) have been given.
8. Deep venous thrombosis prophylaxis has been instituted (if indicated).
9. Implementation of aseptic technique has been reviewed.
10. Procedure duration and anticipated blood loss are checked.
11. Other areas of concern during surgery by any member of the surgical team are noted.

After completion of the procedure a postsurgical evaluation is performed by the surgical team. This portion of the surgical safety checklist includes:

1. Sponge and needle counts are correct.
2. Review of the surgical consent confirms completion of all planned procedures.
3. Pathology specimens will be properly sent to the lab.
4. Plans for postanesthesia recovery have been made and personnel have been notified of the patient’s forthcoming arrival.

All team members must be full participants in the “time-out” procedure. Failure to perform these well-established procedures puts the patient at risk for grave error and brings into question the quality of care being provided to the patient.

The sociology of the plastic surgery operating room

The American Society of Plastic Surgery and the American Society for Aesthetic Plastic Surgery have promoted a “patient-first” initiative in advocating for safety in the operating room. Advances in surgical technique and perioperative medical management have allowed improved clinical outcomes. As much as our medical knowledge increases, we sense a great disappointment when the clinical outcome is not as good

as expected. Attempts at regulation of the surgical environment, with accreditation of surgical facilities, have certainly increased the quality of documentation during surgery, but have they improved outcome? Accreditation of a surgical facility includes reviewing processes and systems but may not actually observe the performance of a single surgery. The accreditation process taking 1, 2, or 3 days evaluates a surgical facility at a point in time. The actual conduct of that facility going forward may not come under scrutiny for another 1–3 years. Compromise in standards by a physician or by the surgical facility may occur slowly and yet soon be so substandard as to put the patient at unnecessary risk. Ultimately, the decision to practice plastic surgery safely will rest with the physician.

The standard of clinical practice in a surgery center or office-based surgical facility must meet or exceed that of an accredited hospital. A series of 10 core principles was published in 2004 advocating the fundamentals of practice for aesthetic surgery.⁴⁷ These same principles are as valid today as when they were first published and should apply to all practitioners and all surgical specialists. Patients should be selected for surgery based on the established criteria set by the ASA classification system. Physicians performing office-based surgery must have admitting privileges at a nearby hospital and a transfer agreement with that hospital facilitating patient transfer and admission when needed. Physicians performing office-based surgery must show competency by maintaining surgical privileges at an accredited licensed hospital or ambulatory surgery center for the same procedures being performed in the office setting. Serious peer review of surgical performance and medical management in an outpatient surgical center or a private surgical facility should be mandatory for the benefit of the patient. Is it appropriate that a physician who is denied privileges at a hospital to perform surgery has the right to open a private facility without peer review and perform those same procedures? Should a privately owned surgical facility function as a hiding place for a physician to escape peer review? The same rules that apply to a practicing surgeon should also apply to the practicing anesthesiologist. No medical practitioner should be above answering to his or her medical peers during a clinical review.

We must begin to question the conduct of clinical practice in the operating room during surgery. A patient can reasonably expect that the focus of the surgical team will be dedicated to performing their jobs to deliver the best possible surgical outcome. Surgical team members (nurses, scrub technicians) who have gone through great effort to maximize the quality and safety of the surgical outcome are not interchangeable with other individuals who have not familiarized themselves with the medical facts of the case. The risk for error increases and the quality of care for the patient decreases when surgical team members change during surgery. No matter how complete the medical “handoff” from one team member to another, no handoff can be as complete as having been in the case from the beginning. Having several different operating room nurses and surgical technicians during a single surgery increases the risk of error and should be discouraged. Continuity of care by the anesthesia care team also improves patient safety. Plastic surgery cases may take a long time and some change in personnel may be necessary during the procedure, but should be minimized. It should not need to be said, but surgery should be performed by the attending surgeon

and designated assistants and not by unlicensed minimally trained individuals deemed “qualified” by the surgeon. A lack of operating room oversight can lead to poor practice quality that may not be detected by a chart and documentation review by a certifying agency.

Best of intentions, not the best of results

Despite the best of intentions on the part of physicians and the healthcare system, errors occurring during hospitalization may cause upwards of 98 000 deaths per year and over 1

million significant injuries. Recent publication of a study showing a failure of new hospital policy and procedures to improve patient safety in a hospital setting is disappointing. Chart review of 2341 randomly selected hospital admissions from 10 randomly selected hospitals between 2002 and 2007 was performed.⁴⁸ In this review, patients were deemed to have been harmed during their hospitalization in 588 instances, about 1 in 4 patients. In 50 of these cases the harm was considered to have been life-threatening, 17 cases resulted in permanent injury and 14 deaths were deemed in part due to medical error. Despite implementation during the study period of policies and procedures to reduce medical error, the error rate remained steady at 25 harms per 100 hospital admissions.⁴⁹

Anesthesia and pain management in plastic surgery

Paul N. Afrooz and Franklyn P. Cladis

SYNOPSIS

- Inadequate pain control may decrease quality of life and delay recovery and the return to normal activities.
- NSAIDs are very efficacious and have a low NNT (number needed to treat).
- Obstructive sleep apnea (OSA) increases opioid sensitivity and appears to increase the risk for postoperative respiratory complications.
- Regional analgesia (epidural, paravertebral, transversus abdominis plane block) reduces postoperative opioid requirements.

Introduction

Pain management before, during, and after any procedure is a key component to successful outcomes in plastic surgery. Consistent patient satisfaction hinges largely upon favorable impressions and recollections of the surgical experience. As such, patient satisfaction and pain management protocols must be effective, dynamic, multimodal, and customizable.

Pain is a self-reported, complex, and subjective experience commonly defined as an unpleasant sensory and emotional experience due to actual or potential tissue damage.¹ The perception of pain involves both the peripheral and central nervous system. Both spinal and supraspinal sites play a role in the perception of pain within the central nervous system. Pain can be generally classified into physiological and pathological pain. Physiologic or nociceptive pain is acute in nature and serves as a warning or protective function, thus promoting healing and rendering it physiologically useful. In contrast, chronic pain (e.g., neuropathic) persists beyond the period of healing rendering it nonprotective and maladaptive; otherwise classified as pathologic pain.

Historically, pain protocols have relied heavily on opioid-based therapies which have several inherent drawbacks. The etiology of pain is often multifactorial, and therefore successful treatment depends on a multimodal approach. Analgesic regimens should target the peripheral nociceptors at the site

of tissue injury, peripheral nerves supplying the surgical area, and both spinal and supraspinal sites. This multi-targeted strategy provides highly effective pain management while minimizing the adverse effects of single-agent strategies.

This chapter will focus on current concepts in pain management in plastic surgery while drawing on several themes, including:

- Multimodal analgesia with an emphasis on opioid reduction
- Neuraxial analgesia such as epidural, paravertebral, and peripheral nerve blocks
- Field blocks
- Systematic extensive surgical site infiltration with long-acting local anesthetics.

Clinical consequences of inadequate pain relief

Despite new strategies and evolving pain management regimens, postoperative pain remains one of the primary concerns of patients undergoing surgery. Approximately 80% of patients report acute pain after surgery with the majority experiencing moderate-to-severe pain.² The clinical manifestations of inadequate pain management include myocardial ischemia, impaired pulmonary function, ileus, thromboembolism, impaired immune function, and anxiety (Table 9.1).^{3,4}

Inadequate management of postoperative pain also results in significant increases in healthcare costs by way of prolonged post-anesthesia care unit stay, delayed discharge, and readmission.⁵⁻⁸ Furthermore, inadequate pain control may decrease quality of life and delay recovery and the return to normal activities.⁹

The clinical impact of inadequate pain control in the perioperative period is significant, casting an array of effects on multiple organ systems. The potential for postoperative wound infections is particularly concerning in plastic surgery. Surgical stress induces an inflammatory reaction and the release of a

Table 9.1 Consequences of unrelieved pain

Cardiovascular	Increased heart rate, peripheral vascular resistance, arterial blood pressure, and myocardial contractility, resulting in increased cardiac work, myocardial ischemia, and infarction
Pulmonary	Respiratory and abdominal muscle spasm (splinting), diaphragmatic dysfunction, decreased vital capacity, impaired ventilation and ability to cough, atelectasis, increased ventilation/perfusion mismatch, hypoventilation, hypoxemia, hypercarbia, increased postoperative pulmonary infection
Gastrointestinal	Increased gastrointestinal secretions and smooth muscle sphincter tone, reduced intestinal motility, ileus, nausea, and vomiting
Renal	Oliguria, increased urinary sphincter tone, urinary retention
Coagulation	Increased platelet aggregation, venostasis, increased deep vein thrombosis, thromboembolism
Immunologic	Impaired immune function, increased infection, tumor spread or recurrence
Muscular	Muscle weakness, limitation of movement, muscle atrophy, fatigue
Psychological	Anxiety, fear, anger, depression, reduced patient satisfaction
Overall recovery	Delayed recovery, increased need for hospitalization, delayed return to normal daily living, increased healthcare resource utilization, increased healthcare costs

Reprinted with permission from Joshi GP, Ogunnaike BO. Consequences of inadequate postoperative pain relief and chronic persistent post-operative pain. *Anesthesiol Clin North America*. 2005;23:21–36

number of humoral mediators along with increased levels of cortisol during surgery. Together, these substances can have detrimental systemic effects including hyperglycemia, catabolism, impaired immune function and wound healing.^{4,10–12} This physiologic and sometimes detrimental stress response to surgery may be mitigated through adequate analgesia.

Acetaminophen, nonsteroidal anti-inflammatory drugs, and cyclooxygenase-2 selective inhibitors

Historically, opioids have been used successfully for pain management in plastic surgery procedures; however, their side-effect profile limits routine use, particularly in ambulatory procedures. For those procedures that do not involve surgical manipulation of major muscle groups or osteotomies, pain management can usually be fulfilled with non-opioid medications such as nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, and local anesthetics.¹³ The advent of cyclooxygenase (COX)-2 selective inhibitors (coxibs), as well as drugs such as gabapentin/pregabalin, clonidine, and low-dose ketamine have added new dimensions in the armamentarium of plastic surgery procedures. See [Table 9.2](#) for dosing.

Acetaminophen

Though less potent than NSAIDs or coxibs, acetaminophen is the most frequently prescribed analgesic for the treatment of acute pain. It is often preferred because it is well tolerated. Despite the similarities to NSAIDs, the precise mechanism of action of acetaminophen is unclear. It is believed to act via inhibition of COX-1 and COX-2 enzymes through metabolism by the peroxidase functions of these enzymes both centrally and peripherally. Additional peripheral effects may be attributable to inhibition of isoforms of COX-1, COX-2, and COX-3 enzymes involved in prostaglandin synthesis, thereby

increasing the pain threshold.^{13,14} Acetaminophen is available in oral, rectal, and IV formulations, and is both analgesic and antipyretic at therapeutic doses with a dose-dependent efficacy. The maximum recommended *daily* dose in adults without hepatic or renal disease is 4 grams with dose reduction recommended in patients with liver insufficiency.

IV acetaminophen produces a rapid and predictable plasma concentration, and is recommended as a first-line agent for the treatment of pain and fever in adults and children if oral administration is not possible.¹³ The analgesic efficacy of acetaminophen has been demonstrated in double-blind clinical trials. Single dose or multiple doses of IV acetaminophen (1 g) were significantly greater than placebo in adult patients who had undergone dental, orthopedic, or gynecologic surgery.

When used in therapeutic doses, acetaminophen is a relatively safe drug with few and mild side effects. In comparison to opioids, there is no effect on respiratory drive, and furthermore, it does not cause sedation, nausea and vomiting or reduced gastrointestinal motility. In addition, the effects on platelets and hemostasis are insignificant in patients without a history of coagulopathy.¹⁵ There are no significant cardiovascular, renal, or pulmonary side effects. The most significant side effect is hepatotoxicity when administered in high doses, chronic use, or when administered with alcohol or other various hepatotoxic drugs. Very rare side effects include blood dyscrasia (i.e. thrombocytopenia), methemoglobinemia, and hemolytic anemia.

Nonsteroidal anti-inflammatory drugs

NSAIDs have been used effectively for the treatment of acute and chronic pain for several decades. The primary mechanism of action is through the inhibition of both COX-1 and COX-2 enzymes, thereby inhibiting the synthesis of thromboxanes and prostaglandins. NSAIDs have well-established analgesic, antipyretic and anti-inflammatory properties. Pharmacokinetic data and selectivity of action are shown in [Tables 9.3](#) and [9.4](#).¹³

Table 9.2 Acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and cyclooxygenase (COX)-2 selective inhibitors dosing

Generic name	Brand name (®)	Dose (mg/kg) Frequency	Maximum ADULT daily dose (mg)	Comments
Acetaminophen (paracetamol)	Tylenol®, Panadol® Ofirmev®	10–15 PO q 4 h (1000 mg, max) 15 IV q 6 h (1000 mg, max)	4000	Lacks anti-inflammatory activity No platelet effects Hepatic failure with overdose
Acetylsalicylic acid (aspirin)	Bayer®, Bufferin®, Anacin®	10–15 PO q 4 h	4000	Inhibits platelet aggregation GI irritability
Ibuprofen	Motrin®, Advil®	5–10 PO, IV q 6–8 h (400–800 mg)	3200	Available as an oral suspension Renal dysfunction GI irritability Inhibits platelet aggregation
Naproxen	Naprosyn®	5–10 PO q 12 h	1500	See Ibuprofen
Ketorolac	Toradol®	IV or IM Load 15–30 mg Maintenance 15 mg q 6 h	120	May be given orally Maximum dose 30 mg Can cause GI upset and ulcers Discontinue after 5 days
Celecoxib	Celebrex®	>25 kg: 100–200 mg (<u>total dose, not mg/kg</u>) PO BID	400	Selective COX-2 inhibitor Less GI distress, less anti-platelet effect Risk of MI in adults with chronic administration

Generally, NSAIDs are very efficacious and have a low NNT (number needed to treat) when used in appropriate doses. Data supports the use of NSAIDs for acute pain management following a variety of ambulatory surgical procedures including plastic and aesthetic surgery. Through a series of meta-analyses, the Cochrane group has demonstrated the analgesic efficacy and safety of single dose NSAIDs, ketoprofen, ketorolac and lornoxicam.^{16,17}

NSAID hypersensitivity as well as cross-reactivity between different drugs have been reported. In patients with a reported history of sensitivity to acetylsalicylic acid, administration of

NSAIDs should proceed with caution. Coxibs may provide a safer alternative; however, cross-reactivity and hypersensitivity in those allergic to NSAIDs is not guaranteed.¹⁸ Celecoxib has a similar structure to sulfonamides and should not be given to patients with a known sulfa drug allergy. NSAIDs are known to cause GI irritation, and GI bleeding. Platelet function is affected, which often results in impaired hemostasis. Furthermore, as a result of prostaglandin inhibition, NSAIDs pose a potential risk for renal insufficiency. Renal insufficiency occurs specifically in the presence of hypovolemia mostly due to perioperative bleeding or dehydration.

Table 9.3 Pharmacokinetic data of acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and cyclooxygenase (COX)-2 selective inhibitors

Drug	Bioavailability	Peak plasma concentration	Plasma half-life	Duration of action
Acetaminophen oral (1 g)	85–95%	10–90 min	2–3 h	4–6 h
Acetaminophen IV (1 g)	100%	5–10 min	2.7 h	4–6 h
NSAID				
Indomethacin (50 mg)	90%	1 h	4.5 h	4–6 h
Ibuprofen (400 mg)	?	1–2 h	2 h	4–6 h
Diclofenac (50 mg)	60–70 %	15–30 min	1.2–2 h	4–8 h
Ketorolac IV (30 mg)	100%	10–15 min	4–9 h	11 h
COX-2 inhibitors				
Etoricoxib (120 mg)	100%	1 h	22 h	20 h
Part-coxib IV (40 mg)	100%	10–15 min	8 h	15 h

Data are presented as average values (data obtained from different sources)

From Gupta A, Jakobsson J. Acetaminophen, nonsteroidal anti-inflammatory drugs, and cyclooxygenase-2 selective inhibitors: an update. *Plast Reconstr Surg.* 2014;134(4 Suppl 2):24S–31S.

Table 9.4 The selectivity of different NSAID and COX-2 inhibitors on the COX-2 and COX-1 isoenzymes

Drug	COX-2/ COX-1 ratio	COX-1/ COX-2 ratio
Aspirin	167	3.1
Naproxen	0.6	1.7
Ketorolac	2	0.5
Diclofenac	2.2	1.4
Indomethacin	30	0.02
Ibuprofen	15	0.007
Piroxicam	33	0.04
Tenoxicam	15	0.62
Meloxicam	0.33	3
Etoricoxib	0.02	344
Celecoxib	0.03	30
Rofecoxib	0.003	272

Cardiovascular side effects include myocardial infarction, particularly with underlying ischemic heart disease. This side effect differs between drugs, with diclofenac posing the greatest risk, and naproxen the least.

Contraindications for NSAIDs, both relative and absolute, are numerous, and discretion must be used in patients with comorbid conditions. However, they remain very effective adjuncts to perioperative pain management. Their routine use in plastic surgery procedures may be precluded due to the minor increase in risk of bleeding and hematoma.¹³

COX-2 receptor inhibitors

Selective COX-2 inhibitors were developed in an effort to reduce the GI side effects and bleeding associated with NSAIDs. Coxibs reduce but do not eliminate the risk for GI bleeding. They are effective in the management of postoperative pain and have a low NNT, but their analgesic effect has not been proven to be superior to traditional NSAIDs. A major advantage of coxibs is their negligible effect on platelet function. The risk of bleeding or hematoma formation is negligible.^{13,19}

The long-term use of coxibs is associated with potential risk for cardiovascular and thromboembolic events. Due to the risk of perioperative myocardial infarction, coxibs should be avoided in patients with ischemic heart disease. There is no difference in the incidence of renal side effects between NSAIDs and coxibs. Overall, coxibs have a lower risk for bleeding complications due to a negligible effect on platelet function, and a lower risk of GI ulcers and bleeding compared to NSAIDs.¹³

Acetaminophen, NSAIDs, and coxibs are effective agents in multimodal perioperative pain management. Acetaminophen has minimal effect on platelet function and can be used safely without any such risk for bleeding or hematoma. It can be administered intravenously, and can reduce the need for opioid analgesics. NSAIDs and coxibs are effective analgesics and demonstrate an additive effect when combined with acetaminophen. While NSAIDs affect platelet function and

increase the risk for bleeding and hematoma, coxibs have minimal risk for bleeding and hematoma formation as well as a lower risk for GI side effects and better tolerance in asthmatics. However, the risk for thromboembolic side effects prevents their use in patients with ischemic heart disease or a history of thrombotic events. Acetaminophen and NSAID/coxib agents in the perioperative period are well established in clinical practice. The exact regimen can be tailored for each individual patient based on risk/side-effect profile of these agents. In combination with other non-opioid analgesics, these drugs can be very effective in pain management in plastic surgery.¹³

Opioids

Opioids are proven to be effective, reliable, and easily titrated in the perioperative period. Current formulations are derived from natural and synthetic sources, and prescriptions of this class of medication are strictly controlled by the Drug Enforcement Agency of the United States. Opioids act mainly on opioid receptors in the spinal cord, medulla and cerebral cortex modifying ascending pain signals and altering the perception of pain. The bound opioid receptors are also responsible for the adverse effects including constipation, sedation, and pruritus.²⁰

In an acute analgesic regimen, opioids may be administered orally or parenterally. Rapidity of onset and predictable plasma levels are advantages of parenteral administration, though disadvantages of IV injection include rapid rise in plasma concentration, and the need for skilled provider administration and observation. Patient-controlled analgesia (PCA) is a modality of delivering opioids that may improve analgesia and patient satisfaction and reduce side effects by decreasing total exposure. It has gained popularity due to an increased safety margin, ease of administration, increased efficacy of analgesia, and decreased provider workload.²⁰ See Table 9.5 for dosing. PCA dosing recommendations are outlined in Table 9.6. These doses may need to be reduced further in patients who are at risk of opioid sensitivity (obesity, obstructive sleep apnea, elderly).

Serious side effects are seen with opioid administration including addiction, as illustrated by nearly 15000 prescription opioid-related overdose deaths in 2008.^{20,21} A significantly increased risk of road trauma is seen with increasing opioid dose.²² Chronic opioid therapy is also associated with a dose-dependent increase in the severity of sleep-disordered breathing.²³ Furthermore, even short periods of exposure to opioids are associated with the risk of opioid tolerance and hyperalgesia which can potentially lead to chronic pain.^{24,25}

Avoiding adverse effects associated with opioids requires implementation strategies for decreasing total opioid doses while maintaining adequate analgesia. Adjuvant medications as well as surgical anesthetic techniques are paramount to dose reduction. Opioids prescribed in the immediate postoperative period should be emphasized as a short-term regimen with transition to non-opioids as soon as appropriate.²⁰ Risk reduction strategies are shown in Table 9.7.

Specific patient populations may be at increased risk for adverse effects with opioid therapy. These include patients with obstructive sleep apnea (OSA) and obesity, elderly patients, and patients on chronic opioid therapy. Obese

Table 9.5 Opioid dosing

Agonist	Equipotent IV dose (mg/kg)	Equipotent PO dose (mg/kg)	Duration (hr)	Oral bioavailability (%)	Comments
Morphine	0.1 (2–4 mg every 2–4 hrs PRN)	0.3	3–4	20–40	“Gold standard”, very inexpensive Histamine release, vasodilation, consider avoiding in asthmatics and in circulatory compromise Poor oral bioavailability; give 3–5 times the IV dose
Meperidine (Demerol®)	1	N/A	3–4	60–80	Catastrophic interactions with MAO inhibitors Tachycardia; negative inotrope Metabolite normeperidine produces seizures 12.5 mg effectively treats shivering Not recommended for routine use
Hydromorphone (Dilaudid®)	0.015–0.2 (0.2–0.5 mg every 2–4 hrs PRN)	0.05	3–4	50–70	Commonly used when morphine produces too many undesirable systemic side effects No histamine release
Fentanyl (Sublimaze®)	0.001 (25–50 mcg every 5–15 min in monitored setting)	N/A	0.5–1		Very effective for short painful procedures Vagotonic and can cause bradycardia Minimal hemodynamic alterations Chest wall rigidity/glottis closure Transmucosal dose 10–15 mcg/kg Transdermal patch available for chronic pain
Codeine	N/A	1.2 (15–60 mg every 4–6 hrs PRN)	3–4	40–70	PO only “Prodrug” must be converted by CYP2D6 to morphine to produce analgesia (ultra-rapid metabolizers can produce excessive amounts of morphine, slow metabolizers no analgesia) Often combined with acetaminophen No longer recommended Contraindicated (“black box warning”) in pediatric tonsillectomy patients
Hydrocodone (Vicodin®, Lortab®)	N/A	0.1 (15–60 mg every 4–6 hrs PRN)	3–4	60–80	PO only (liquid and tablet) Only available in combination with acetaminophen DEA class 2 drug
Oxycodone (Tylox®, Percocet®, Oxycontin®)	N/A	0.1 (5–10 mg every 4–6 hrs PRN)	3–4	60–80	PO only Often prescribed with acetaminophen but available as a single agent Liquid formulation 1 mg/mL and 20 mg/mL (potential for catastrophe with wrong formulation) Sustained release tablet available, which cannot be crushed or chewed (Oxycontin®) High abuse potential in sustained release formulation

Table 9.6 PCA dosing guidelines

Drug	Continuous basal infusion (mg/hr)	Demand dose (mg)	Lockout interval minutes (range)	Number of demand doses/hr (range)	4-hour limit (mcg/kg)
Morphine (standard 1 mg/mL)	0.5–1 Rare in adults	1	8 (6–15)	5 (1–10)	250
Fentanyl	0.025–0.05 Rare in adults	0.025	15 (6–15)	4 (1–10)	5
Hydromorphone (standard 0.2 mg/mL)	0.2 Rare in adults	0.2	8 (6–15)	5 (1–10)	50

patients have a higher incidence of OSA secondary to increased soft tissue in and around the pharynx and larynx. This leads to upper airway obstruction and the propensity for disordered breathing during sleep. OSA is estimated to affect 9–24% of middle-aged adults.²⁶ Through a variety of mechanisms, opioids may contribute to airway obstruction, apnea, and hypoxemia. Opioids have a dose-dependent effect on genioglossus tone, which can contribute to airway obstruction.²⁷ The sedative effect of opioids may also contribute to airway closure²⁸ while also altering the arousal thresholds that remain critical in postapneic recovery. Furthermore, postoperative lung volumes are reduced in OSA patients causing upward movement of the diaphragm and carina.²⁹ This reduction in airway length is associated with increased propensity for airway obstruction.³⁰ Postoperative sleep-disordered breathing is related to opioid dose, and some patients with OSA may be more sensitive to opioids.^{31,32} While apneic episodes are likely to be witnessed and corrected in the post-anesthesia care unit, these episodes may go unrecognized on the ward where the nurse-to-patient ratio is lower and patients are monitored less closely.²⁰ Postoperative desaturation is fairly common among this population, and cardiorespiratory complications occur with increased frequency.^{33–36} Cutting the opioid dose in half or increasing the dosing interval with prolonged observation may be prudent to avoid adverse effects. Respiratory failure in OSA patients is transient and ventilatory support is typically needed for 24 hours postoperatively.³⁴ Early utilization of positive airway pressure therapy in the postoperative period is associated with a significant reduction in the incidence of respiratory failure, intubation, and intensive care utilization.^{37–40} Recommendations for postoperative care in this group of patients includes the use of continuous pulse oximetry, opioid restriction, increased length of PACU observation, and early postoperative positive airway pressure therapy.⁴¹

The aging surgical population necessitates an understanding of the effect of opioid administration in these patients. The pharmacokinetics and pharmacodynamics of all medications including opioids may change significantly in the elderly patient. Changing circulating plasma volume and changes in body weight composition may lead to a variable effect. Adverse effects that may be tolerated in younger patients may have more profound effects in the elderly. The addition of opioid side effects may increase the likelihood of falls in the elderly, which can lead to multiple complications with a higher degree of morbidity and mortality. Additional opioid

side effects may contribute to increased all-cause mortality. Furthermore, the elderly are at risk of long-lasting cognitive dysfunction postoperatively from anesthesia independent of postoperative opioid dosing with 17% of patients experiencing dysfunction at 3 months.⁴² Opioid dosing has not been found to have a direct link to cognitive dysfunction postoperatively. Side effects in conjunction with anesthesia increase the risk for cognitive complications. Adjuvant anesthetics play a key role and have been used with much success in reducing opioid administration by 15–55% in the first 24 hours postoperatively. Adjunctive medications such as acetaminophen, NSAIDs, and α -2 agonists may be a mainstay in therapy for the elderly population, lending to adequate anesthesia and limited exposure to opioids.⁴²

It is not uncommon that patients who present for surgery are taking opioids for various reasons. It is important to determine the drug, dose, frequency, and duration in developing a postoperative pain regimen in such patients. Patients who have been taking opioids for a period in excess of 6 months are considered chronic opioid users and are likely to have a tolerance to analgesia and some side effects.²⁰ Additional acute dosing above baseline chronic dosing must be considered while exercising caution because of dose-dependent side effects. Furthermore, patients who have chronic pain and use chronic opioids have more postoperative pain and resolve pain more slowly than opioid-naïve patients.⁴³ Chronic nonmalignant pain is a complicated pathology that may be managed best by consultation with a pain specialist.

Some chronic opioid users adhere to special regimens or drugs including methadone or suboxone. Methadone is used as a long-acting opioid, as well as a drug to facilitate weaning from opioids.⁴⁴ Larger doses may be used for withdrawal prevention. It is essential to determine methadone indications, and communication with the prescribing physician to delineate the analgesic plan for the patient postoperatively.²⁰

Buprenorphine is a unique opioid that tightly binds the opioid receptor, but elicits low activity.⁴⁵ This agent can also be used for chronic pain and opioid addiction. Similar to methadone, discussion with the prescribing physician is essential to allow tapering if indicated. Discussion with the anesthesiologist is also imperative as standard opioid regimens may not be effective immediately postoperatively. Close monitoring is necessary as discontinuation of buprenorphine can lead to increased sensitivity to opioids and the concurrent adverse effects.²⁰

Table 9.7 Summary of adverse effect reduction strategies for opioids in special situations

Description	Risk modification
IV PCA	Opioid reduction strategies: intraoperative and postoperative strategies including adjuvant medications (acetaminophen, ketamine, magnesium, NSAIDs, α 2-agonists, gabapentinoids, and liposomal bupivacaine) and techniques (surgical technique modification and regional and neuraxial anesthesia) Limit/avoid other sedatives
Oral opioids	Limit postoperative prescription and close follow-up Limit/avoid other sedatives Patient education on adverse effects, warning signs Adjuvant medications (acetaminophen, α 2-agonists, gabapentinoids, NSAIDs, and liposomal bupivacaine)
Obesity, OSA	Preoperative screening for OSA Preoperative consideration for polysomnography Opioid reduction strategies: intraoperative and postoperative strategies including adjuvant medications (acetaminophen, ketamine, magnesium, NSAIDs, α 2-agonists, gabapentinoids, and liposomal bupivacaine) and techniques (surgical technique modification and regional and neuraxial anesthesia) Avoid other sedatives (anxiolytics and sleep aids) Consider extended monitoring, although controversial Early postoperative positive airway pressure therapy if significant desaturation occurs Advise sitting or head up reclining posture when sleeping postoperatively
Elderly patients	Opioid reduction strategies: intraoperative and postoperative strategies including adjuvant medications (acetaminophen, ketamine, magnesium, NSAIDs, α 2-agonists, gabapentinoids, and liposomal bupivacaine) and techniques (surgical technique modification and regional and neuraxial anesthesia) Adjuvant analgesia (local, regional, or neuraxial anesthesia, modified surgical technique, and non-sedative analgesics) Avoid other sedatives
Opioid tolerant	Continue chronic opioids High-dose opioid taper Opioid reduction strategies: intraoperative and postoperative strategies including adjuvant medications (acetaminophen, ketamine, magnesium, NSAIDs, α 2-agonists, gabapentinoids, and liposomal bupivacaine) and techniques (surgical technique modification and regional and neuraxial anesthesia) Patient education and establish expectations

NMDA receptor antagonists and gabapentinoids

Ketamine

Ketamine works as a noncompetitive *N*-methyl-D-aspartate (NMDA) receptor antagonist. The NMDA receptor is activated with sustained and intense pain stimuli, and has been implicated in both immediate hyperalgesia and long-term changes in pain perception that may lead to chronic postsurgical pain (CPSP).^{46,47} Ketamine has also been shown to downregulate proinflammatory pathways, which may be the mechanisms responsible for antihyperalgesia effects.^{47,48}

Ketamine has a half-life of 180 minutes and is metabolized in the liver, and its unique characteristics include the preservation of respiratory drive and hemodynamic stability.^{47,49} The favorable profile of ketamine as an anesthetic agent includes continuous spontaneous breathing as it has minimal respiratory depressant effects and preserves upper airway muscle, pharyngeal, and laryngeal tone. Further favorable characteristics include a mild sympathomimetic effect that results from catecholamine release, and an inhibition of noradrenaline reuptake leading to an increase in heart rate, stroke volume,

and mean arterial pressures.^{46,50} This profile is favorable in hemodynamically unstable patients.

Recent data have demonstrated that ketamine improves analgesia and reduces opioid requirements in the perioperative setting.^{51–54} Furthermore, evidence supports the intraoperative use of ketamine in patients with chronic pain and those on chronic high-dose opioids. Reports demonstrate reduced postoperative pain, as well as reduced opioid consumption.⁵⁵ The use of ketamine has also been associated with a significant reduction of opioid-related side effects including postoperative nausea and vomiting (PONV).^{51,52} Dose-dependent neuropsychiatric effects, including dysphoria, hallucinations, vivid, unpleasant dreams, and catatonia or psychoses are potential side effects of ketamine rendering it unfavorable as a sole anesthetic agent. However, subanesthetic doses have a considerably lower incidence of these adverse effects and seem to be well tolerated.⁴⁹

There is a lack of data with regard to the use of ketamine in plastic surgery patients; however, many conclusions can be extrapolated from the literature and other patient populations. Low-dose ketamine as an adjunct is most beneficial in surgeries where postoperative pain is expected to be high.⁵¹ The sympathomimetic effects in conjunction with decreased intraoperative and postoperative opioid requirements may help to preserve hemodynamic stability and decrease the

need for perioperative vasopressor use. Decreasing the need for perioperative vasopressor use would be ideal for flap perfusion.⁴⁹

At subanesthetic doses (0.5 mg/kg bolus or 0.1 mg/kg/h), ketamine improves analgesia and reduces opioid requirements. This effect seems most significant in surgeries that are expected to be painful and have a moderate and high degree of pain. Furthermore, the sympathomimetic effects may be beneficial in maintaining hemodynamic stability. Psychiatric side effects such as dysphoria and hallucinations seem to be far less common than with anesthetic doses of ketamine (1–5 mg/kg), and are reported by multiple authors to be well tolerated.⁴⁹

Gabapentinoids

Gabapentin and pregabalin are alkylated analogs of gamma-aminobutyric acid (GABA). Gabapentin was originally developed as an anticonvulsant.⁴⁶ Neither of these agents exert their clinical effects by way of the GABA-A or GABA-B receptors. Instead, they seem to bind voltage-gated calcium channels of cortical and dorsal horn neurons, attenuating the release of the neuropeptides glutamate, norepinephrine, and substance P.^{46,50} Furthermore, gabapentin may activate descending inhibitory noradrenergic pathways that regulate the neurotransmission of pain signals in the dorsal horn.^{50,56}

Gabapentin has been used successfully in several neuropathic pain states including complex regional pain syndrome, multiple sclerosis, and postherpetic neuralgia.^{57–61} Pregabalin has also been found to be useful in diabetic neuropathy.⁶² Both agents are only available as oral preparations and differ in bioavailability.

Several studies have concluded that both gabapentin and pregabalin reduce both postoperative pain and opioid use postoperatively. Overall the gabapentinoids are well tolerated with the most common transient adverse effects of somnolence, dizziness, headaches, balance problems, peripheral edema, sweating, dry mouth, and nausea and vomiting.^{46,50,63,64} There remains some debate about the timing and dose of administration. Higher preoperative doses seem to provide better analgesia although sedation may be seen. The optimal duration of postoperative administration remains to be determined. The overall risk–benefit ratio is likely to favor their use in procedures that are expected to be painful or that might cause acute neuropathic pain.⁴⁹

Local anesthetics

Major improvements in local anesthetic injection and application techniques have allowed surgeons more flexibility. Minimizing pain with injection has led to an increase in convenience while maintaining patient safety and comfort. The wide-awake approach without sedation has proven to be effective in hand surgery,⁶⁵ cosmetic surgery,⁶⁶ facial skin cancer reconstruction,⁶⁷ and adult cleft lip repair⁶⁸ among others.

Minimizing pain with injection of local anesthesia (Box 9.1)

Blunt-tipped cannulae have been shown to be effective for the infiltration of HA fillers in sensitive areas with minimal pain.⁶⁹

BOX 9.1 Tips for minimizing pain with injection of local anesthesia

- Create skin perforation with a 27-gauge needle
- Switch to a 30-gauge blunt-tipped cannula for injection when possible
- To promote painless injection of local anesthesia with sharp needles:
 1. Buffer lidocaine and epinephrine with 8.4% sodium bicarbonate
 2. Warm the local anesthetic
 3. Distract the patient or area of injection with pressure or soft pinch near the point of injection
 4. Use smaller 27- or 30-gauge needles
 5. Stabilize the syringe with both hands to avoid movement of the needle
 6. Inject 0.5 cc perpendicular to the dermis, and subdermally, followed by a pause until the patient reports no further needle pain
 7. Inject an additional 2 cc before moving the needle followed by moving and injecting in an anterograde fashion slowly with 1 cm of local anesthetic palpable or visible ahead of the needle
 8. Always reinsert needles within 1 cm of blanched areas
 9. Have patients frequently provide feedback and pain scores during the injection process

Following skin perforation with a 27-gauge needle, a fine blunt-tipped 30-gauge cannula is introduced. This method allows for the painless passing of cannulae beneath the skin for injection of large areas with local anesthesia with little to no pain. Furthermore, far less ecchymosis results without the use of a sharp needle tip.⁷⁰

Injecting local anesthesia with traditional sharp needles in an almost painless manner is readily achievable.^{68,71} When injecting with sharp needles, the pain of injection can be mitigated by (1) buffering lidocaine and epinephrine with 8.4% sodium bicarbonate; (2) warming the local anesthetic; (3) distracting the patient or the area of injection (pinch or pressure near the injection point); (4) using smaller 27- or 30-gauge needles; (5) stabilizing the syringe with both hands to avoid movement of the needle; (6) injecting 0.5 cc perpendicularly subdermally followed by a pause until the patient reports no further needle pain; (7) injecting an additional 2 cc before moving the needle followed by moving and injecting in an anterograde fashion very slowly with 1 cm of local anesthetic palpable or visible ahead of the needle; (8) reinserting needles within 1 cm of blanched areas; and (9) having patients provide feedback and scores by relaying pain during the injection process.⁶⁷

Liposomal delivery of local anesthetics

Liposomal bupivacaine offers long-lasting local anesthesia by means of sustained, gradual delivery. With exposure over time, the vesicular network opens successively thereby releasing the local anesthetic content. With liposomal bupivacaine in Exparel (Pacira Pharmaceuticals, Inc, San Diego, CA), 3% of the bupivacaine is initially free at the time of injection for an immediate effect as with traditional bupivacaine, while the

remainder is contained within the vesicles for gradual delivery.⁷⁰ While there is evidence purporting a potentially positive early experience with liposomal bupivacaine for wound infiltration, further evidence for its use in plastic surgery is needed. In particular, it is not FDA-approved for epidural or peripheral nerve block administration and these routes of administration are currently being investigated.

Local anesthetic infiltration into operative sites (wound infiltration)

The injection of bupivacaine into TRAM flap donor sites decreases opiate requirements in the 72 hours postoperatively.⁷² In another study, patients who received bupivacaine (0.375%) infused at 4 mL/h used less mean patient-controlled anesthesia narcotic in the immediate 48 hours postoperatively, and transitioned to oral narcotics earlier than control patients. Overall pain satisfaction scores were significantly improved in the continuous infusion group in comparison to the control group.⁷³ Furthermore, ropivacaine injection into cleft palate incision sites demonstrated significantly improved postoperative pain scores at all observational periods in comparison to the control groups.⁷⁴

Local anesthetic infiltration via a wound catheter and a pain pump have shown favorable outcomes in other specialties.⁷⁵ With respect to plastic surgery, there is evidence to show that bupivacaine wound catheters reduce narcotic use, nausea and vomiting, and increase overall pain satisfaction scores.^{73,76} Further studies are necessary to elucidate the advantages of routine catheter usage in plastic surgery. Maximum dosing recommendations for different anesthetic techniques are outlined in [Table 9.8](#).

Tumescent analgesia in plastic surgery

Tumescent analgesia (TA) delivers a very dilute anesthetic subcutaneously in a large volume of fluid. This form of local anesthesia is used most commonly in liposuction, but may be used in a variety of procedures to reduce intraoperative and postoperative pain, and decrease the need for additional anesthetics and narcotics. The added benefit of dilute epinephrine causes vasoconstriction and significantly limits blood loss.

TA was popularized in the 1990s by Klein for use during liposuction.⁷⁷ Currently, TA can be used alone or in conjunction with other forms of anesthesia. When used in conjunction with other modalities, TA offers several of the ascribed advantages of multimodal anesthesia.

Tumescent analgesia has been reported in a wide array of surgical procedures including:

- Liposuction
- Subcutaneous mass excision and scar revisions
- Excisional body contouring (abdominoplasty, body lifts, brachioplasty, thigh lifts)
- Breast augmentation, reduction, mastopexy, gynecomastia, and capsular contracture revision
- Mastectomy
- Burn excision and skin grafting
- Skin procedures (dermabrasion and laser resurfacing)
- Face and neck lifts
- Hair grafting
- Lower extremity varicose vein stripping and endovascular ablation
- Lymph node dissections

Table 9.8 Maximum local anesthetic dosing guidelines

Amide drug (concentration range)* and technique concentration range	Spinal	Caudal/lumbar epidural	Peripheral	Subcutaneous
Lidocaine (0.5%–2.0%) (0.5–1.0% infiltration) (1–2% peripheral, epidural, subcutaneous) (5% spinal)	1–2.5	5–7 [§]	5–7 [§]	5–7 [§]
Bupivacaine (0.0625–0.5%) (0.125–0.5% infiltration) (0.25–0.5% peripheral, epidural, subcutaneous)	0.3–0.5	2–3 [§]	2–3 [§]	2–3 [§]
Ropivacaine (0.0625–0.5%) (0.125–0.5% infiltration) (0.2–0.5% peripheral, epidural, subcutaneous)	0.3–0.5	2–3 [§]	2–3 [§]	2–3 [§]
Prilocaine (0.5–1% infiltration) (1–1.5% peripheral) (2–3% epidural)	NR	5–7 ^{§#}	5–7 ^{§#}	5–7 ^{§#}
Intra-arterial or intravenous injection of these doses may result in systemic toxicity or death. *Concentrations are displayed in mg percent. Example, a 1% solution contains 10 mg/mL, a 2% solution contains 20 mg/mL. §The higher dose is recommended only with the coadministration of epinephrine 1:200,000. Maximum epinephrine dose for adults under general anesthesia with volatile agents is 2–3 mcg/kg. #Total adult dose should not exceed 600 mg.				

- Thyroidectomy
- Hernia repair

Fluid composition

Several TA fluid formulas have been described⁷⁷⁻⁷⁹ and are based on either 1000 mL of 0.9% saline or Lactated Ringer's solution.⁸⁰ Lidocaine is the most frequently used local anesthetic in tumescent fluid, however various local anesthetics have been used. A combination of lidocaine and bupivacaine has been described in abdominoplasty combined with liposuction without any complications.⁸¹ In patients with liver dysfunction, care should be taken with dosing as the amide agents (lidocaine, bupivacaine, ropivacaine) are metabolized by the liver. Furthermore, while lidocaine and bupivacaine can safely be used in combination, there is little guidance with respect to the upper limits of dosing when used in combination.⁸⁰

The reported dose limitation for lidocaine with epinephrine is 7 mg/kg; however, doses of 35 mg/kg are frequently used during liposuction,⁷⁷ and up to 55 mg/kg have been reported without complications.⁸² Peak lidocaine blood levels occur 10–14 hours following infiltration.⁸³ In highly vascularized areas, such as above the clavicle, plasma lidocaine levels peak at approximately 6 hours after injection.⁸⁴ Due to peak plasma concentrations occurring several hours following injection, patients may experience toxicity well after the procedure has been completed and following discharge.

Epinephrine in tumescent analgesia

The maximal hemostatic effects of epinephrine occur 25 minutes after administration rather than the commonly held belief that this occurs at 7–10 minutes.⁸⁵ However, only a minimal improvement in the hemostatic effect is achieved after 15 minutes. Epinephrine has a 2–3 minute half-life, and therefore there are no clear dosing guidelines when used in TA. An upper limit of 10 mcg/kg has been suggested but this depends on cofactors like the co-administration of volatile anesthetic agents. Arrhythmias can develop in adults under general anesthesia with isoflurane, sevoflurane or desflurane with as little as 2–3 mcg/kg. Pediatric patients appear to tolerate 10 mcg/kg under volatile anesthesia without arrhythmias. Epinephrine should be avoided in patients with pheochromocytoma, hyperthyroidism, severe hypertension, cardiac disease, or peripheral vascular disease.⁸⁶

Complications of tumescent anesthesia

Though complications are rare, one must be aware of possible complications particularly in high volume tumescent infiltration. Lidocaine is commonly used in doses of 35–55 mg/kg and this is considered safe in TA. Cardiac monitoring is suggested with doses over 35 mg/kg as lidocaine toxicity can cause cardiac and neurologic complications. In cases of high volume infiltration, extended monitoring is suggested due to peak plasma levels occurring 10–14 hours after administration. Signs and symptoms of lidocaine toxicity include restlessness, drowsiness, light-headedness, metallic taste in the mouth, tinnitus, slurred speech, and peri-oral numbness and tingling. At higher plasma levels, shivering, muscle twitching, tremors, convulsions, central nervous system

depression, coma, respiratory depression, and cardiac arrest may occur.^{80,86}

In the event of local anesthetic toxicity, the following steps must be taken:

1. Stop infusion of fluids with local anesthetic
2. Assure airway management and oxygenation
3. Call for help
4. Prepare for seizure suppression with benzodiazepines
5. Manage cardiac arrhythmias as per ACLS protocol but do not use lidocaine
6. Administer 20% Intralipid 1.5 mL/kg (may need to repeat up to 10 mL/kg) then infuse 0.25 mL/kg/h if cardiac effects persist
7. Isolated neurologic events (seizures) can be treated with benzodiazepines (midazolam, diazepam, or lorazepam) or propofol. Propofol should NOT be used as a lipid substitute for cardiac arrest.

High tumescent fluid injection volumes may lead to intravascular fluid overload with cardiac and pulmonary consequences. With high infusion volumes, administration of other fluids must be titrated. In patients with cardiac, pulmonary, or renal compromise who are at higher risk for fluid overload, the volume of TA administration must be limited.⁸⁰

In large volume liposuction, mild hyponatremia and hypokalemia may occur. This is rarely a clinical concern, but nevertheless, one must be aware of this potential problem in large volume liposuction.⁸⁷ Furthermore, large volumes of room temperature tumescent fluid may lower body temperature. Therefore, in cases prone to hypothermia, such as large volume, and large surface area, tumescent fluid should be warmed to 37°C, in addition to other warming measures to avoid hypothermia.⁸⁰

Regional and neuraxial analgesia in plastic surgery

Regional analgesic modalities deliver local anesthetics to groups of peripheral nerves outside the central nervous system, thereby blocking sensation to specific dermatomes. Neuraxial techniques deliver local anesthetic and analgesic agents directly or indirectly to the spinal cord or neuraxis. The benefits of regional and neuraxial techniques parallel those of multimodal anesthesia and include improved pain control, decreased narcotic use, and narcotic-associated side effects, shorter hospital stays, and better patient-reported outcomes.⁸⁸

Paravertebral block

The paravertebral block (PVB) involves the injection of a local anesthetic into the paravertebral space. The thoracic paravertebral space is triangular in shape and is bordered anteriorly by the parietal pleura, medially by the vertebral column, and posteriorly by the superior costotransverse ligament. The nerve root divides into dorsal and ventral rami as it exits the neuroforamen. Ventral rami become the intercostal nerves that provide sensation to the abdomen and chest wall. This targets the nerve root as it emerges from the neuraxis (Fig. 9.1), thereby providing ipsilateral analgesia in the specific

Fig. 9.1 Paravertebral anatomy. (Adapted from Momoh AO, Hilliard PE, Chung KC. *Regional and neuraxial analgesia for plastic surgery: surgeon's and anesthesiologist's perspectives*. *Plast Reconstr Surg*. 2014;134(4 Suppl 2):58S–68S.)

dermatomal segments.⁸⁸ In contrast to neuraxial analgesic techniques, the central nervous system is usually avoided along with the associated complications such as hypotension, urinary retention and bradycardia.

Long-lasting analgesia can be achieved by inserting a catheter into the paravertebral space to provide continuous infusion of local anesthetic in the early postoperative period.^{89,90} Depending on the location of the block, this technique can be used in breast, thoracic, and abdominal procedures. Indications and contraindications for paravertebral and neuraxial blocks are outlined in [Table 9.9](#). While PVBs facilitate outpatient surgical management and early discharge by providing long-lasting analgesia with few side effects, this technique poses a risk for pneumothorax due to the proximity of the lung to the paravertebral space. Although this risk is less than 1%, this potential complication is likely a major

reason for the limited use of PVBs in outpatient plastic surgery procedures. Use of ultrasound guidance helps avoid this complication. Additional complications include epidural spread, hypotension, bradycardia, and intravascular injections may cause toxicity.⁸⁸

Transversus abdominis plane block

The transversus abdominis plane (TAP) block places a long-acting local anesthetic in the fascial plane between the transversus abdominis and the internal oblique ([Fig. 9.2](#)). This technique blunts the afferent sensory component of the terminal branches of intercostal nerves resulting in analgesia of the abdominal wall. In the traditional TAP block, the tenth thoracic (T10) through first lumbar (L1) terminal branches are the nerves typically targeted. The fascial plane between the

Table 9.9 Indications and contraindications for regional and neuraxial techniques

Technique	Performed by	Indications	Contraindications
Paravertebral block	Anesthesiologist	Thoracic and abdominal surgical procedures Use as primary anesthetic or as adjunct to primary anesthetic Inpatient and ambulatory surgery procedures Rescue analgesia after failure of oral or parenteral analgesia Early postoperative mobilization desired	Patient refusal Coagulopathy or bleeding diathesis Localized infection at injection site Allergy to local anesthetics Prophylactic anticoagulation therapy* Inability to communicate with patient*
Transversus abdominis block	Anesthesiologist or surgeon	Lower abdominal surgical procedures Adjunct to primary anesthetic Inpatient and ambulatory procedures Early postoperative mobilization desired	Patient refusal Localized infection at injection site Allergy to local anesthetics
Epidural	Anesthesiologist	Thoracic, abdominal, and lower extremity surgical procedures Use as primary anesthetic or as adjunct to primary anesthetic Indwelling catheter for postoperative analgesia limited to inpatient procedures only	Patient refusal Coagulopathy or bleeding diathesis Localized infection at injection site Systemic infection Allergy to local anesthetics Elevated intracranial pressure Severe hypovolemia Severe aortic or mitral stenosis Prior back surgery at injection site* Prophylactic anticoagulation therapy* Inability to communicate with patient*

*Relative contraindication

From Momoh AO, Hilliard PE, Chung KC. Regional and neuraxial analgesia for plastic surgery: surgeon's and anesthesiologist's perspectives. *Plast Reconstr Surg.* 2014;134(4 Suppl 2):58S–68S.

transversus abdominis and internal oblique is a relatively avascular plane and this may account for the slow drug clearance and subsequent prolonged duration of analgesia.^{91,92} The TAP block can be performed intraoperatively by anesthesiologists or surgeons with ultrasound guidance percutaneously or directly through exposed fascia (Fig. 9.3). The TAP block is typically used in combination with other anesthetic modalities as its primary analgesic effects are within the abdominal wall and may not address visceral pain associated with intra-abdominal procedures.⁸⁸

The ultrasound probe is placed within the lumbar triangle of Petit, the boundaries of which are the costal margin superiorly, the iliac crest inferiorly, the external oblique anteriorly, and the latissimus dorsi posteriorly. Local anesthetic is then infiltrated in the fascial plane between the internal oblique and transversus abdominis. Catheters may be placed for continuous or intermittent infusion. A subcostal approach to the TAP block is also possible and provides analgesia to the supraumbilical abdomen (T7–T9). The subcostal TAP block is unlikely to be used alone as most abdominal procedures in plastic surgery also involve the lower abdomen.⁸⁸

Though complications are rare with the TAP block, they include hematoma and intraperitoneal injection with injury to intra-abdominal organs.^{93–95}

Neuraxial analgesia

Spinal and epidural anesthesia

Spinal anesthesia is a neuraxial blockade of spinal nerve roots as they travel through the subarachnoid space. This type of

Fig. 9.3 (A) Intraoperative, ultrasound-guided delivery of TAP block. Note concurrent inset of flap in background. (B) Ultrasound scan of transversus abdominis plane (TAP) block. block is also frequently referred to as a subarachnoid block, or intrathecal injection. This technique provides rapid and deep anesthesia below the level of the block, and is generally confined to shorter procedures of the lower extremities or pelvis, therefore limiting its utility in a large portion of plastic surgery procedures.

Epidural anesthesia blocks the spinal nerve roots outside of the subarachnoid space (Fig. 9.4). It has a wide range of applications including operative anesthesia, obstetric and postoperative analgesia, and chronic pain management. The epidural technique is advantageous because it allows a catheter to be placed in the epidural space anywhere along the neuraxis to provide continual analgesia via infusion. Thoracic epidurals may spare motor nerves to the lower extremities as well as micturition pathways, thereby allowing for early ambulation and the avoidance of prolonged urinary catheter use. An epidural may be used as the primary anesthetic for surgery, but typically this requires high doses of local anesthetic and is often combined with other modalities.⁸⁸ The epidural is an excellent form of analgesia for surgery involving the lower extremities, particularly reconstruction with microvascular work. The sympathectomy may provide an advantage by enhancing blood flow to the extremity.

Lumbar neuraxial procedures are performed with the patient in the seated position (Fig. 9.5). Full neck and back flexion overcomes lumbar lordosis by widening the gap between adjacent lumbar spinous processes. This opens the interlaminar space and facilitates access to the neuraxis. The L3/L4, L4/L5, or L5/S1 interspaces are frequently chosen for analgesia of the pelvis and lower extremities. It is prudent to place a Foley catheter and implement fall precautions when epidurals are used in the postoperative period.⁸⁸

Complications of the epidural blocks are typically related to technique or physiologic effects of the neuraxial injection. Complications related to technique include spinal headaches, transient paresthesias, peripheral neuropathy, epidural abscesses, and epidural hematomas. Physiologic complications include cardiovascular, respiratory, thermoregulatory, and urogenital sequelae.

Cardiovascular effects are not uncommon and typically include hypotension with an incidence as high as 33%.⁹⁶

Cardiovascular sequelae are primarily due to efferent sympathetic blockade leading to an uncompensated decrease in systemic vascular resistance. A decrease in preload in conjunction with an unopposed vagal influence leads to a decreased heart rate and cardiac output.⁹⁷ Hypotension and bradycardia are usually mild and readily respond to treatment.⁸⁸

Respiratory complications typically occur as a result of blockade of the intercostal and abdominal muscles needed for forceful exhalation. Inhalation remains unaffected as the diaphragmatic innervation is spared. While accessory muscles are not essential for expiration in healthy patients, those with pulmonary disease such as asthma or COPD may be prone to complications. Therefore, careful patient selection is crucial, as is the preparedness to manage these potential complications.⁸⁸

The majority of regional and neuraxial techniques are better established in other surgical fields including general surgery, urologic surgery, and gynecologic surgery. However, applications in plastic surgery are increasing. These techniques are best implemented in collaboration with anesthesiologists.⁸⁸

Fig. 9.5 Placement of a thoracic epidural block for postoperative pain control. (From Barrington MJ, Scott DA. *Do we need to justify epidural analgesia beyond pain relief?* 2008;372:514–516. © Lancet 2008.)

Summary

One of the most common concerns reported by patients prior to surgery is the presence of postoperative pain.² Evidence reveals that adequate postoperative analgesia is only achieved in a minority of patients.⁹⁸ Furthermore, reports in the United States reveal that 86% of adult surgical patients experienced pain after surgery, of which 75% had moderate-to-severe pain in the immediate postoperative period, and 74% experienced similar levels of pain after being discharged home.⁹⁹ These findings reveal that advances in surgical and analgesic techniques have had minimal clinical effect on postoperative pain management.¹⁰⁰

It is well established that unrelieved postoperative pain is linked to adverse physiologic changes that may increase adverse postoperative outcomes including morbidity and mortality.³ Furthermore, limitations in movement secondary to pain can prolong rehabilitation, reduce health-related

quality of life, and delay return to normal daily activities.^{5,100–103} Increased cost of care, prolonged hospital length of stay, readmissions, or unexpected admissions, and patient dissatisfaction are common consequences of these adverse outcomes.^{104–106}

The concept of multimodal analgesia was developed with the understanding that postoperative pain is a complex and multifactorial phenomenon. As such, combinations of analgesics of different classes acting upon various target sites may provide superior pain relief with a lower incidence of adverse effects.^{107–109} The goal of multimodal analgesia is to improve pain relief while reducing opioid requirements and the adverse effects of opioids or any other single agent.

Future considerations include establishing sufficient evidence for multimodal analgesia in plastic surgery while optimizing analgesic regimens. Use of patient-specific and procedure-specific pain management strategies should improve pain control, and perioperative outcomes including rehabilitation and return to activities of daily living.

Evidence-based medicine and health services research in plastic surgery

Claudia R. Albornoz, Carolyn L. Kerrigan, E. Dale Collins Vidal, Andrea L. Pusic, and Amy K. Alderman

SYNOPSIS

The key take-home messages from this chapter are how to:

- Gather existing evidence on outcomes
- Interpret evidence on outcomes
- Design new studies to add evidence on outcomes
- Identify and analyze existing sources of data to create new evidence on outcomes
- Capture the patients' perspective on outcomes
- Recognize the importance of an essential dimension of evidence: the patients' perspective
- Consider the cost dimension in achieving outcomes
- Understand the challenges and approaches in translating good evidence into daily clinical practice.

Physicians must make complex decisions in situations of uncertainty – often with incomplete, inaccurate, or outdated information. The goal of outcomes research is to improve the information available to make these complex decisions. It is important to understand that measuring outcomes is not just about the final result of our interventions. More importantly, it is a means by which we gather evidence to improve decision-making, the processes of care, and the systems in which we work. Maximizing patient care and surgical outcomes requires continuous efforts to identify information needs and to produce the best evidence to fulfill these needs.

The best evidence – where do we find it?

There are two ways to obtain best evidence for decision-making to improve quality of care (Fig. 10.1). The first is to evaluate existing data and identify those reports that are convincing based on a good study design and clinically meaningful outcomes. When the current evidence is inadequate, the second choice is to produce new credible evidence. This section

will describe a structure for evaluating existing evidence and then introduce methods for producing best evidence.

Evaluating existing literature

Best evidence requires three things: (1) a good study design; (2) an appropriate statistical analysis; and (3) clinically meaningful outcome measures. In a thorough review, Offer and Perks¹ have enumerated the challenges that plastic surgeons face when trying to practice evidence-based medicine. They cite the lack of quality evidence in our literature as a major factor. Even a superficial perusal of our journals makes it clear that they are replete with descriptions of procedures by individual surgeons and the “outcomes” of those procedures in that surgeon's hands. These studies, known as case reports or case series, have limited applicability to other practices, and are not structured, not compared, and not randomized. This is not only weak evidence on which to make medical decisions, but it is not an acceptable way to make such decisions in this era of healthcare reform and pay for performance (P4P).² As shown in Fig. 10.1, the stronger the evidence, the better the care one is able to deliver.

Literature search strategies

Practicing evidence-based medicine involves searching for the best available research, appraising the relevant studies for validity, and then translating the evidence to optimize patient care.³ Many clinical questions remain unanswered because of problems formulating relevant questions, insufficient access to information resources, and a lack of search skills.⁴ Today, there are a variety of strategies and web-based resources that allow searches of the relevant literature to answer many clinical questions. Some examples are provided below.

PubMed

The US National Library of Medicine provides access to more than 16 million citations through PubMed, accessing references from MEDLINE and directly from journals. Information

Fig. 10.1 Improved care is linked to better evidence.

from PubMed searches has been shown to improve both patient care and health outcomes significantly.⁴

Clinical Queries

Clinical Queries is a feature of PubMed that can help identify citations with the study design of interest. It is able to link the type of question (e.g., intervention, diagnosis, natural history, and outcome) to a search strategy that specifies the desired study design.⁴

PICO

The critical first step in the pursuit of evidence-based medicine is to ask a well-formulated question. Without sufficient focus and specificity, an otherwise relevant and important clinical question can be mired in irrelevant evidence. When the PICO framework is used with the PubMed Clinical Queries (see above), it has been shown to improve the efficiency of the literature search. The acronym PICO stands for patient problem, intervention, comparison, and outcome, and is a strategy to pose a well-formulated question.⁴ In a literature search for evidence in plastic surgery, for example, a question framed using the PICO approach might be expressed this way: In patients undergoing breast reduction (P), preoperative antibiotic prophylaxis (I) versus no prophylaxis (C), what is the rate of postoperative infections (O)?

Meta-analysis

Conceptually, a meta-analysis is the summation of multiple qualitative studies in order to increase the sample size, thus strengthening the conclusions over that which can be drawn from an individual article. This analysis allows researchers to reach a more reliable conclusion when there are conflicting results from multiple studies.⁵ Ideally, a meta-analysis is conducted using the highest level of evidence, such as randomized controlled clinical trials. Although meta-analysis can also be conducted on cohort studies and even case series, the quality of the evidence and, therefore, the conclusions are weaker.

Meta-analysis has some disadvantages. First, meta-analysis has been criticized for both overly broad inclusion criteria and, conversely, for overly strict inclusion criteria. Either may result in degradation of the results. Inclusion criteria that are overly broad may lead to inclusion of studies of lesser quality or with less reliable results. Very strict inclusion criteria may mean that the studies that are included have limited generalizability. Another disadvantage is that meta-analyses are costly and require a significant time commitment from the research team.

The technique of meta-analysis may have limited applicability in plastic surgery, where there are few randomized trials and the metrics from one study to another may vary considerably. An example of a meta-analysis can be seen in Fig. 10.2.⁶ This figure demonstrates an analysis of randomized trials evaluating the impact of tamoxifen on survival. As the reader can observe, there are multiple studies, with the findings of each plotted on a central axis. The summary analysis, which incorporates data from these studies, appears at the bottom of the vertical axis and suggests a benefit for the use of tamoxifen in early breast cancer. As can be seen, the 95% confidence interval for that summary measure is quite narrow. This implies a better point estimate of the true benefit of tamoxifen. Also note that the quality of the individual study is used to determine its weight in computing the summary score.

More recently, researchers conducted a meta-analysis of randomized controlled trials comparing rates of capsular contracture using either smooth or textured implants. These authors identified seven randomized controlled trials that addressed this issue. Individually four of the seven studies did not find a statistically significant decrease in the rate of contracture with textured implants. However, when the results of the studies were pooled, the meta-analysis suggested that textured implants had lower rates of contracture.⁷ To see further examples of good-quality meta-analyses, the reader is referred to the online Cochrane reviews.⁸

Systematic reviews

Systematic reviews are evaluations of the literature conducted according to clearly stated, scientific research methods that are designed to minimize the risk of bias and the errors associated with traditional literature reviews. The review process includes a comprehensive search based on defined criteria and includes a thorough evaluation of the quality and validity of the studies identified in the search process.⁹

The best-known source for systematic reviews is the Cochrane Database of Systematic Reviews, which contains over 3600 completed reviews.⁸ The Cochrane Group also provides a handbook for systematic reviews of interventions which prescribes seven steps for preparing a review:

1. Structuring the question
2. Identifying possible studies for inclusion
3. Evaluating selected studies
4. Data collection and synthesis
5. Analyzing results
6. Discussing the findings
7. Updating reviews

Systematic reviews are influential tools in supporting evidence-based practice and some consider them to provide stronger evidence than randomized controlled trials. Moreover, they are essential for summarizing existing data, thereby

Review: Tamoxifen for early breast cancer
Comparison: 01 Adjuvant tamoxifen versus control
Outcome: 02 Mortality (death from any cause)

Fig. 10.2 Meta-analysis of randomized controlled trials evaluating the impact of adjuvant tamoxifen on survival risk among women with early breast cancer. (Early Breast Cancer Trialists' Collaborative Group. *Tamoxifen for early breast cancer. Cochrane Database of Systematic Reviews. 2001:4.*) Multiple studies have been included, with the findings of each plotted on the central axis. Data are represented as an odds ratio. (Odds ratio, similar to relative risk, reports the proportion of an occurrence to a nonoccurrence.) The summary analysis, which incorporates data from these studies, appears at the bottom of the vertical axis and suggests a benefit for the use of adjuvant tamoxifen in early breast cancer.

avoiding the wasted effort that would result from unnecessary duplication of previous studies.⁹ To see further examples of good-quality systematic reviews, the reader is referred to the online Cochrane reviews.

Study design and levels of evidence

Broadly, study designs can be divided into experimental and observational studies. Experimental studies, which include randomized controlled clinical trials, patient preference trials, and large, multicenter trials, test a hypothesis by examining the impact of an intervention on the outcome. In contrast, observational studies, which include cohort studies, case-control studies, case series, and case reports, describe the natural history or incidence of disease or analyze associations between risk factors and the outcomes of interest. As one might expect, there is generally a direct correlation between the complexity of a study design and the quality of the resulting data (Table 10.1).

Experimental studies

Randomized controlled clinical trials

The randomized controlled clinical trial is perhaps the most complex of the experimental study designs and is the standard to which all others must be held. The design of the randomized controlled trial evolved over the course of many years and each component of the design attempts to minimize the influence of study bias and confounders on the results. The ultimate goal is to create a sample population that is truly representative of the whole. In this way, the results of a limited trial can be generalized to the population at large with confidence.

According to the National Institutes of Health, clinical trials are conducted in four phases, each serving a different purpose and helping researchers answer different questions (Table 10.2). In phase I, researchers evaluate an experimental drug or intervention in a small number of test subjects (20–80) to evaluate its safety, determine a dose–response curve, and identify potential side-effects. In phase II, the experimental drug or intervention is given to a larger group of subjects (100–300) to test its effectiveness and further evaluate its safety profile. In phase III, the experimental drug or intervention is given to a much larger group of subjects (1000–3000) in order to “confirm its effectiveness, monitor side effects, compare it to commonly used treatments, and collect information that will allow the experimental drug or treatment to be used safely”. In phase IV, post-marketing surveillance is continued to identify additional information on the risks, benefits, and optimal use of the intervention.¹⁰

Unfortunately, randomized controlled trials are expensive and often impractical to answer questions that compare one surgical intervention to another.^{11,12} While patients are often willing to be randomized to take a pill versus a placebo, few are willing to be randomized to one of two surgical procedures or to a sham procedure. Further, surgeons often have a strong preference for one type of surgery over another and are therefore unwilling to randomize patients.¹³

Although the randomized controlled clinical trial is considered the “gold standard”, it is not without limitations. For example, the underlying assumptions of randomized controlled clinical trials may be invalid. The preferable treatment between two alternatives may be unclear; evidence of treatment effects from other sources may be insufficient; only specific effects resulting from the intervention are therapeutically valid; and only when the trial’s inclusion and exclusion criteria match the characteristics of an individual patient can

Table 10.1 Levels of evidence

Level of evidence	Type of study	Key features
Level I	Randomized controlled trial	Two randomly selected groups, one serving as a control, with a blinded comparison of outcomes of an intervention
Level II	Prospective and retrospective cohort studies	A single group followed over time and evaluated for risk factors relative to outcome or incidence of disease
Level III	Case-control study	Two groups, one with and one without disease, with a comparison of risk factors relative to outcomes
	Well-designed clinical study	Experimental study design with an intervention and a control arm compared for outcomes
Level IV	Cross-sectional cohort study	A single group evaluated at a single point in time for disease prevalence or risk factors
	Case series	A single group of consecutive cases identified by a disease or condition and followed over time
Level V	Expert opinion	Opinion based on experience and review of literature
	Case reports	A small group identified by a disease or condition and followed over time

(Adapted from the American Society of Clinical Oncology.)

the outcome of the study be fully transferred to clinical practice.¹¹ In addition, randomized controlled clinical trials are inadequate to study infrequent or delayed adverse events; they are difficult, if not impossible, to conduct for the study of rare diseases; and although the benefits and harms of an intervention may be well recognized, its extent or significance is not always well assessed.¹²

Alternatives to randomized controlled clinical trials

In practice, randomized controlled clinical trials often pose logistical challenges and ethical problems, which limit sample sizes.^{14,15} Therefore, alternatives to randomized controlled clinical trials are needed.

Patient preference trials

When patients or surgeons have strong treatment preferences and refuse randomization, patients may be willing to participate in a preference trial. A preference trial is a trial in which the patient is offered the treatment options rather than random assignment. Patients who have a clear preference are given

their preferred treatment while patients without a preference are randomized.^{16–18} Thus both randomized and nonrandomized patients are studied together under the same protocol other than the treatment assignment.

There are a range of opinions as to the validity and usefulness of this study design. Some researchers believe they complement, rather than replace, randomized controlled clinical trials. Preference trials have been criticized for results that may not be generalizable due to the inherent bias in allowing patients with a strong preference to select their own treatment. Patients who prefer a specific treatment may be more compliant than others who have no such preference. This, and other potential impacts of a patient's preference on actual outcome, is not yet a well-understood bias that can be accounted for. In addition, particularly in small studies, there is the inability to control fully for potential confounders that may differ significantly between treatment groups.¹⁷ Proponents of preference trials believe that subjects who choose their treatment may be more representative of patients in actual clinical practice and that they can provide insights into the patient decision-making process.¹⁶

Large multicenter trials

When an insufficient number of patients are enrolled in a randomized controlled clinical trial, researchers may choose to use large multicenter trials to increase the sample size.¹⁶ A multicenter controlled clinical trial carries the same requirements as a single-center trial and each site must follow the same protocol, with identical inclusion and exclusion criteria, randomization strategies, interventions, and methods for collecting and evaluating the outcomes.¹⁴ Nevertheless, some researchers have found variability in surgery and surgical techniques in multicenter trials.¹⁶

Observational studies

Given the difficulty of executing a randomized controlled trial, the next best level of evidence is produced by a good experimental study or well-designed cohort study, with the

Table 10.2 Four phases of clinical trials

Phase	Purpose
I	To test an experimental drug or treatment in 20–80 people to evaluate safety, determine a safe dosage range, and identify side effects
II	To test the experimental drug or treatment in 100–300 people to determine effectiveness and evaluate its safety
III	To test the experimental drug or treatment in 1000–3000 people to confirm effectiveness, monitor side effects, compare it to commonly used treatments, and collect information to allow for its safe use
IV	Postmarketing studies to learn more about the drug's or treatment's risks, benefits, and optimal use

Fig. 10.3 In the prospective cohort study, the investigator develops a hypothesis about variables that may impact the outcome under investigation, collects data about those risk factors, and then follows the cohort for development of the outcome of interest. For example, when the association between smoking and lung cancer was suspected, a prospective study design increased the strength of that causal association. While prospective studies lend credence to causal associations, they are expensive and generally require years of follow-up.

former having some, but not all, the features of a randomized controlled trial. Although there is widespread belief that observational studies are less valid, often overestimating the magnitude of treatment effects, there are at least several reports suggesting that good observational studies can provide the same level of internal validity as randomized trials.^{19,20}

Cohort studies

Cohort studies evaluate a group or cohort at risk for disease. The evaluation may occur over time or at a single point in time. The latter is further described as a cross-sectional cohort study and is often used to collect data on the prevalence of disease. The second common use of cohort studies is to analyze the exposures that put subjects at risk for disease or interventions that reduce that risk. This requires an evaluation of the cohort at a minimum of two points in time. The study may be designed prospectively (Fig. 10.3) or retrospectively (Fig. 10.4). In the prospective cohort study, the investigator develops a hypothesis about variables that may impact the outcome under investigation, collects data about those risk factors, and then follows the cohort for development of the outcome of interest. For example, when the association between smoking and lung cancer was suspected, a prospective study design increased the strength of that causal association.

While prospective studies lend credence to causal associations, they are expensive and generally require years of follow-up. Retrospective studies have similar goals, but identify the cohort at risk in the present and investigate the risk factors or exposures that occurred in the past. This is often

done by subject recall or chart analysis, both of which are flawed when compared to prospective data collection. Data collected in this manner are more likely to be incomplete, inaccurate, inconsistent, or subject to recall bias. On the other hand, the major advantages of retrospective studies are that they can be done in a relatively short timeframe and are much less costly than prospective studies.

Case-control studies

Case-control studies (Fig. 10.5) differ from cohort studies in that two distinct groups of subjects are investigated. The first group (case) is selected by the presence of disease and the second (control) by its absence. In contrast, a single population at risk for disease is studied in a cohort design. Like cohort studies, the case-control design may be prospective or retrospective. The major strength of the case-control study is in the investigation of rare conditions or prevalence of disease and its increased susceptibility to bias. Controls may be concurrent or historic, matched (on key variables such as age and sex) or unmatched.

Case series and case reports

As defined above, cases are simply a collection of subjects that have been identified by the presence of a disease or condition. In our literature, these are frequently reported based on a specific intervention. If the collection of subjects is large and

Fig. 10.4 In the retrospective cohort study, the investigator identifies a cohort, collects data about those exposures or risk factors that occurred in the past, and then examines the association between risk factors and outcomes. For example, when the association between smoking and lung cancer was suspected, a retrospective study design supported the hypothesis but failed to show a causal association. In retrospective studies, data collection is often done by subject recall or chart analysis, both of which are flawed when compared to prospective data collection. The major advantages of retrospective studies are that they can be done in a relatively short timeframe and are much less costly than prospective studies.

Fig. 10.5 Case-control studies differ from cohort studies in that two distinct groups of subjects are investigated. The first group (case) is selected by the presence of disease and the second (control) by its absence. Like cohort studies, the case-control design may be prospective or retrospective. The major strength of the case-control study is in the investigation of rare conditions or outcomes. Its weakness lies in the inability to assess incidence or prevalence of disease and its increased susceptibility to bias.

consecutive (case series), it may provide valuable information about indications and contraindications for surgery and expected outcomes. If the cases are nonconsecutive (case reports), it raises concerns about sampling bias, such as patient self-selection or surgeon's recall bias, that may dilute the ability of the study to capture the true indications and outcomes. The value of case reports lies in their ability to present a new idea, a new surgical approach, and refinement of existing surgical techniques and to communicate rare adverse events.

Large-database analysis

Population-based research

Effectiveness versus efficacy

Evaluating surgical outcomes is necessary in order to provide high-quality care, patient safety, and informed patient choice. Surgeons must have up-to-date reliable information about surgical risks and outcomes that can be transferable to their own patient population. Surgical outcomes data from single-surgeon or single-center studies demonstrate the efficacy of a procedure performed by a particular surgeon but do not provide data on the effectiveness of a procedure performed by different surgeons in diverse patient populations.

Clinicians need to have information on an intervention's outcomes under real-world conditions, not just in the optimal setting.^{21,22} As we discussed in the prior section, case series and clinical trials performed across a few academic centers are at risk for selection bias, and the results represent outcomes under optimal conditions. National databases, on the other

hand, include patients and physicians from all types of health-care settings, allowing assessment of outcomes in the "real world". This was demonstrated with the randomized clinical trials for carotid endarterectomy procedures (Fig. 10.6).²² The clinical trials reported a very low mortality rate for these procedures. However, after the clinical trials concluded, the mortality following carotid endarterectomy was substantially higher than that reported in the trials, even among those institutions that participated in the randomized studies. Mortality with carotid endarterectomy was also found to be inversely proportional to a center's volume. Thus, clinical trials generally do not represent real-world surgical outcomes.²² An alternative, research using a national database, is a population-based approach that provides information on a procedure's effectiveness under real-world conditions rather than just its efficacy in ideal situations.

The importance of power

Adequate sample size is another key component to outcomes research. True differences in outcomes can only be detected when research studies are adequately powered through a large-enough sample size.^{23,24} Plastic surgery faces the challenge of being a relatively low-volume group of providers compared to other specialties, such as those treating cardiovascular disease. Outcomes studies with small patient samples are often underpowered and at risk for a type II, or B, error. This statistical error happens when a study does not find a statistically significant difference between treatment groups when a difference truly exists (lack of statistical power).²⁵ Chung *et al.* found more than 80% of "negative studies" in the *Journal of Hand Surgery* had powers of less than 0.80 to detect a 25% difference between treatment groups. There was a greater than 20% risk of missing a true difference between treatment groups when a study had less than 0.80 power. The primary reason for the low power among these studies was insufficient sample size.²⁶ Large-database analyses can provide sufficient sample size to avoid an underpowered study.

Table 10.3 illustrates the importance of an adequate sample size in outcomes research. In this theoretical example, imagine

Fig. 10.6 Mortality rates following carotid endarterectomy in patients enrolled in a randomized controlled trial (trial hospitals) compared to those not enrolled in a study and operated on at hospitals with high, medium, and low volumes of endarterectomy cases. (Adapted from Wennberg DE, Lucas FL, Birkmeyer JD, *et al.* Variation in carotid endarterectomy mortality in the Medicare population: trial hospitals, volume and patient characteristics. JAMA. 1998;279:1278-1281.)

Table 10.3 Understanding the relationship between sample size and statistics

	Sample size	Number of complications	Complication rate (%)
Large physician group	48500	1500	3
Plastic surgeons	46	4	8
Difference is not statistically significant			
Large physician group	48500	1500	3
Plastic surgeons	46	0	0
Difference is not statistically significant			
Large physician group	48500	1500	3
Plastic surgeons	100	0	0
Difference is not statistically significant			

a large group of physicians having performed a cosmetic procedure on 48500 patients with 1500 complications (3% complication rate). Imagine a small group of plastic surgeons having performed the same procedure on 46 patients, and 4 had a complication (8% complication rate). This is not a statistically significant difference due to the small number of procedures performed by the plastic surgeons. Imagine, in a similar example, the complication rate for the large group of physicians remains at 3% (1500 patients with a complication) and, due to a slight change in sampling, the plastic surgeons had no complications on 46 patients (0% complication rate). This is also not a statistically significant difference because the study was underpowered in regard to the number of patients treated by plastic surgeons. In fact, the study sample could increase to 100 patients for the plastic surgeons with no complications and still there would not have been a statistically significant difference between provider groups.

Data sources

Clinical registries

Large databases in healthcare can be generally described as either a clinical registry or administrative claims data (Table 10.4). Clinical registries are designed for the purpose of collecting clinical data and have the advantage of providing detailed patient and treatment information. Many national clinical registries are disease-specific, such as the Surveillance Epidemiology and End Results (SEER) registry and the National Comprehensive Cancer Network (NCCN) that monitor outcomes in cancer patients. Plastic surgery has a national clinical registry called Tracking Operations and Outcomes for Plastic Surgeons (TOPS), which is supported by the American Society of Plastic Surgeons and the American Board of Plastic Surgery. The primary purpose of TOPS is to facilitate monitoring the quality of surgical care in plastic surgery. These types of clinical registries can be invaluable to researchers who are interested in studying patient populations that may not be captured in claims data, such as younger patients not captured in Medicare or self-pay cosmetic

patients. Researchers should be aware of the potential limitations of data sources. For example, the SEER registries only capture information within the first 4 months of initial treatment, and the TOPS database relies on voluntary physician-reported data. However, a recent study supports the validity of the TOPS database.²⁷

Administrative claims data

Administrative data, also known as “claims data” or “discharge data”, are collected for billing purposes and lack detailed patient information found in clinical registries. The data are available from several different sources, including hospitals, states, and payers. The content usually represents only one episode of care, unlike a clinical registry. The data are commonly in a uniform format called a hospital discharge abstract, which includes: a patient identifier, hospital identifier, demographic information (age, gender, race, payer), admission acuity (emergent, urgent, elective), length of stay, hospital charges, discharge status (death, transfer, extended care, home), primary/secondary diagnoses and procedures. Outcomes data from administrative sources are generally limited to mortality, length of stay, and charges. Data accuracy is better for primary procedure codes, diagnosis codes, demographics, and outcomes and less accurate for secondary diagnoses, which makes risk adjustment difficult.

It is not possible to use claims data to evaluate cosmetic procedures since these procedures are self-pay. Researchers have used information from CosmetAssure to evaluate cosmetic surgery outcomes.²⁷ CosmetAssure is an insurance policy sold nationally that covers medical and surgical complications from cosmetic surgery. There is a financial incentive to report a covered complication. However, clinical outcomes collected in the database are limited and patient-reported outcomes are not included.

How to use large databases for research

Administrative data can be a good starting point for a research project since the data are readily available and often inexpensive. The data source can also provide a large sample size that can help when studying a rare event or condition. The research question must take advantage of the strengths of the data for the project to be successful. Advantages of administrative data include population-based data that can be used to assess regional variations in care, real-world outcomes, and epidemiological trends.

Small-area variation

Prior to the 1970s, the rate of surgery for a population could not be determined, and data were limited to the number of cases performed at a given institution or by a specific surgeon. In 1973, Wennberg and Gittelsohn published a method for estimating the population served by a medical center, which allowed for the first time the calculation of procedure rates (e.g., the number of tonsillectomies per 100000 people served).^{28,29} We now know that certain surgical procedures demonstrate wide and unexplained variations in regional and national rates (e.g., hysterectomy, prostatectomy, caesarean section) whereas other procedures are performed at similar rates (e.g., appendectomy, cholecystectomy). In general, those procedures whose risks and benefits are well established

Table 10.4 Examples of clinical registries and administrative claims data

Data source	Description
Clinical registries	
Surveillance, Epidemiology and End Results (SEER) registry	Sponsored by the National Cancer Institute and collects data on cancer incidence and survival for approximately 26% of the US population (http://seer.cancer.gov/registries/)
National Comprehensive Cancer Network (NCCN)	Alliance of the leading cancer centers in the US that are dedicated to improving the quality of cancer care (http://www.nccn.org)
National Surgical Quality Improvement Program (NSQIP)	Program is sponsored by the American College of Surgeons and includes academic and private-sector hospitals which desire to participate. Data include inpatient and outpatient visits among patients undergoing major surgical procedures (https://www.facs.org/quality-programs/acs-nsqip)
Tracking Operations and Outcomes for Plastic Surgeons (TOPS)	Program is sponsored by the American Society of Plastic Surgeons, the Plastic Surgery Educational Foundation, and the American Board of Plastic Surgery. Board-certified plastic surgeons may participate. Inpatient and outpatient data are collected (https://tops.plasticsurgery.org)
Administrative claims data	
State–federal partnerships	State healthcare organizations submit datasets to the Agency for Healthcare and Research Quality (http://www.ahrq.gov)
State Inpatient Database	
Nationwide Inpatient Sample	
Kids Inpatient Database	
State Ambulatory Surgery Database	
Medicare¹⁵⁰	
Part A	Inpatient hospital discharge abstracts
Part B	Outpatient claims data
Veterans Affairs (VA) data	
Patient Treatment File (PTF)	Inpatient hospital discharge abstracts
Outpatient Care Files (OCF)	Outpatient visits at VA-based clinics
CosmetAssure¹⁵¹	Insurance company that covers complications related to cosmetic surgery

exhibit the least variability. Procedures with high variability suggest that the optimum management has yet to be established or adopted. Although small-area variations allow us to make observations about differences in procedure rates, they do not help explain these variations or tell us which rate is right. What it does suggest is that a more definitive evaluation needs to be undertaken to identify the optimal treatment strategy.³⁰ The Dartmouth Atlas of Health Care is one of the best examples of how to use administrative data to examine variations in the rates of surgery in the US using data from the national Medicare database, provider files, and American Hospital Association.³¹

Volume–outcome analysis

Another field of investigation that falls under the broad heading of large-database analysis is the area of volume–outcome studies. There is growing evidence to suggest that surgical outcomes are better at high-volume institutions.³² The reason may in part be due to the skill of the surgeon but also reflects the hospital and systems that support a given population of patients. A landmark paper by Birkmeyer *et al.*³³ described a significant correlation between surgeon volume and operative mortality in the US using Medicare

data. Another example is the work by Roohan *et al.*³⁴ on the 5-year survival of patients with breast cancer treated at low-, moderate-, and high-volume centers (Table 10.5). This work shows that there is as much as a 30% difference in the 5-year survival between low- and high-volume hospitals. In plastic surgery, the volume–outcome relationship has been analyzed for autologous breast reconstruction, identifying that centers with higher volumes have lower likelihood of complications.^{35–37}

Table 10.5 Volume–outcome association for 5-year survival after breast cancer treatment

Hospital volume	Breast cancer cases/year	5-year survival risk ratio
Very low	1–10	1.60
Low	11–50	1.30
Moderate	51–150	1.19
High	>150	1.00
(Adapted from Roohan PJ, Bickell NA, Baptiste MS, et al. Hospital volume differences and five-year survival from breast cancer. <i>Am J Public Health</i> . 1998;88:454–457.)		

Large cohort studies

Large-database analysis has played a key role in cohort studies. This allows relatively rare events to be analyzed with a large sample size, giving greater statistical significance and power to the analysis. It often involves linking multiple databases to examine risk factors or exposures relative to outcomes. The outcomes measured most often are mortality and cancer, as both are frequently tracked through various regional and national registries.

Epidemiology

Large databases are also useful tools to evaluate trends over time in surgical utilization and outcomes for a population. For example, the Nationwide Inpatient Sample (NIS) was used to document a dramatic increase in the use of bariatric surgery in the US.³⁸ The national SEER database has been used to assess sociodemographic differences in receipt of postmastectomy breast reconstruction³⁹ and assess trends in the use of breast reconstruction after the Women's Health and Cancer Rights Act.⁴⁰ Initial studies found that the overall use of breast reconstruction across the US was low, and that race/ethnicity is a significant predictor of receipt of postmastectomy reconstruction. More recent studies, using the NIS database, have shown that the rate of immediate breast reconstruction increased from 20 to 38% from 1998 to 2010, with a shift in the method of reconstruction from autologous to implant.⁴¹

Examples of large-database analyses in plastic surgery

Many large national and state databases have had limited applications for plastic surgeons.^{42,43} The most obvious reason is that many of the procedures performed by plastic surgeons are not captured in these databases. For example, the Medicare database captures only patients older than 65 years who use Medicare as the primary payment mechanism.

Several authors have used these databases to garner information useful to plastic surgeons. Gittelsohn and Powe used data from the state of Maryland to compare rates of elective surgery, such as septoplasty, rhinoplasty, reduction mammoplasty, and blepharoplasty.⁴⁴ Significant variations were noted in rates of surgery. Explanatory variables were explored, and the authors concluded that income and race were significant predictors of surgery. Keller *et al.* have looked at variations in the rate of surgery for carpal tunnel syndrome in the state of Maine.⁴⁵ They were able to identify a 3.5-fold difference in rates, and the authors concluded that the major driving factor is physician decision-making. We do not know the "right" rate of carpal tunnel surgery, but the data provided by studies such as this will enable us to begin to ask the appropriate questions.

Large databases have provided the source for cohort investigations on the relationship between breast reduction and a reduced risk for development of breast cancer. Boice *et al.*⁴⁶ identified breast reduction patients in Sweden using hospital discharge data linked with Swedish registries for cancer, death and emigration, and compared results with expected breast cancer incidence in the general population using the Swedish Nationwide Cancer Registry. The investigators found that women 7.5 years after reduction mammoplasty were at a statistically significant 28% decreased risk of cancer. The

Fig. 10.7 The graph displays differences in overall complications for breast augmentation between single and combined procedures in the Tracking Operations and Outcomes for Plastic Surgeons database. Complications for combined procedures represent overall rates of a complication and cannot be assigned to a particular procedure. The rates of all the complications between single and combined procedures were significantly different ($P < 0.01$) using Pearson chi-square. DVT, deep venous thrombosis; PE, pulmonary embolism.

NCCN database has been used to evaluate the association between postmastectomy breast reconstruction and the delivery of adjuvant chemotherapy for breast cancer patients.⁴⁷ The authors found that immediate postmastectomy breast reconstruction does not appear to lead to omission of chemotherapy, but it is associated with a modest, but statistically significant, delay in initiating treatment. Breast reconstruction trends have been investigated using the NIS database. The authors identified increasing use of immediate reconstruction after the passage of the WHCRA in 1998, especially using implants. The increased use of implant-based reconstructions was associated with increasing bilateral mastectomies, especially for contralateral prophylactic mastectomies.^{41,48} Additional aspects of breast reconstruction have been studied, such as the association of sociodemographic variables with the method of breast reconstruction, the relationship between hospital volume and outcome for autologous reconstruction, and the economic implications of the use of microsurgery and bilateral flaps.^{35,49,50} Regarding cosmetic procedures, the TOPS and CosmetAssure databases have been used to assess outcomes with abdominoplasty and breast augmentation procedures.²⁷ The low complication rates found in this study support the safety of these procedures when performed by plastic surgeons. However, the authors stress that surgeons should be aware of the overall higher complication rates associated with combining breast augmentation with other procedures (Fig. 10.7). In summary, these represent just a few examples of the potential use of large databases in plastic surgery research.

Patient-reported outcomes research

Definition of terms

In plastic surgery research, attention is increasingly being placed on understanding the patient's perception of the surgical result and the impact that surgery has on quality of life (QoL). To appraise and demonstrate the benefits of a chosen surgical technique or alternate treatment adequately, it is important for plastic surgeons to understand the available approaches to measurement of patient-reported outcomes (PRO).

Patient satisfaction and QoL may be measured using specially designed questionnaires, known as PRO measures or PROMs. This term applies specifically to a questionnaire used in a clinical or research setting where responses are collected directly from patients. These questionnaires quantify QoL and/or significant outcome variables (e.g., patient satisfaction, symptoms) from the patient's perspective. PROMs provide a means of gaining insight into the way patients perceive their health and the impact treatments have on their QoL. A good PROM should evaluate the impact of disease, trauma, surgical or nonsurgical intervention on various aspects of a patient's day-to-day life in a manner that is scientifically sound and clinically meaningful.⁵¹

In plastic surgery research, many of the PROMs frequently employed in studies to evaluate surgical outcomes have not been developed and validated using acknowledged guidelines.^{51–54} Such PROMs are considered *ad hoc* questionnaires, and although they may pose clinically reasonable questions, one cannot be confident about their reliability (ability to produce consistent and reproducible scores) or validity (ability to measure what is intended to be measured). The use of such measures, however, has been extensive in plastic surgery. As an example, in a systematic review to identify PROMs developed for use with breast surgery patients, our team identified 65 *ad hoc* measures.⁵² PROMs that can be used in any patient group regardless of their health condition are called “generic questionnaires”, which allow direct comparisons across disease groups, or between sick and healthy groups. These measures can provide important information for health policy decisions. For example, research using the Short Form 36 (SF-36) – the most widely used generic measure in the world⁵⁵ – with breast reduction patients shows that women report clinically important differences in QoL compared with women in the general population.^{56–59} In the US, breast reduction is a procedure for which health insurance companies frequently dispute payment; it is thus useful to place the health burden experienced by women with breast hypertrophy into the context of patients with other medical conditions (e.g., women with hip or knee osteoarthritis seeking joint replacement).

However, there are limitations associated with the use of generic measures. Given their generic nature, they sometimes lack sensitivity to the particular concerns of a patient group. For instance, the SF-36, which measures physical, emotional, and social functioning, does not include questions about sexuality, body image, or satisfaction with breast appearance, which are clearly important concerns of breast reduction patients.⁶⁰ Generic measures, like the SF-36, may then not evaluate the most important issue for a particular patient group. Disease- or condition-specific questionnaires address problems specific to a single disease or treatment group. Such measures, when developed through in-depth patient interviews, can help to identify issues of importance to a specific group of patients. As these measures include content areas that are more relevant to a given patient group, they are more likely than generic measures to be sensitive to measuring changes in specific aspects of health. However, in general they cannot be used to make comparisons across different patient groups.

An additional challenge is that, in plastic surgery, there are many areas for which condition-specific instruments have been either inadequately developed or not developed at all.^{52–54} This situation is rapidly being remedied with the

development of new plastic surgery-specific questionnaires. As an example, the BRAVO study,⁶¹ which evaluated the effectiveness of breast reduction surgery, was conducted in 2001 using the Breast Reduction Symptoms Questionnaire. This questionnaire only provided an evaluation of symptom relief. Since then, the science of PRO measurement has evolved and new measures, such as the BREAST-Q,⁶² provide a comprehensive appraisal, including satisfaction with breast appearance and psychosocial well-being.

Essential elements for PROMs

PROMs must be clinically meaningful and scientifically sound. A questionnaire that is clinically meaningful addresses those issues considered important to patients and their surgeons. Scientific soundness refers to the demonstration of reliable, valid, and responsive measurement of the outcome of interest. A reliable measure yields consistent and reproducible results of the same measure. Reliability is an important property of a PROM because it is essential to establish that any changes observed between patient groups are due to the intervention or disease, and not to problems in the measure (Fig. 10.8). Test–retest reliability may be evaluated by having individuals complete questionnaires on more than one occasion over a time period when no changes in outcome are expected to have occurred. The degree to which individual responses remain the same is reported statistically as Cronbach's alpha⁶³ and intraclass correlation coefficients.⁶⁴

Validity is the ability of an instrument to measure what we intend it to measure (see Fig. 10.8). The distinction between reliability and validity is important because, just as reliability does not imply validity, the inverse is also true. That is, a reliable measure will always yield the same score, but it may not be valid, as it may not necessarily measure what it is meant to measure. Establishment of validity may be considered an ongoing process. The measure is looked at from various perspectives, including an assessment of the development process, consideration of known group differences, evaluation of internal consistency and of convergent and discriminant validity relative to other existing measures.

Fig. 10.8 Reliability and validity. The quality of any standardized survey is judged by its reliability and validity. The reliability is traditionally measured by test–retest; the validity is a measure of accuracy. Looking at it simplistically, reliability is the ability to hit the same spot repeatedly on the target, whereas validity is the ability to hit the bull's eye repeatedly.

Responsiveness is defined as the ability of a measure to detect significant change accurately. If a PROM is used to evaluate changes as the result of a surgical procedure or to follow patients over time, the measure must be sensitive to change. Responsiveness is examined by measuring outcomes, before and after an intervention, and by evaluating the measure's sensitivity to change.

Overview of PROM development

To choose a QoL measure for use in a study or in clinical practice, prospective users should take into account the process used to develop PROMs. Knowing how a PROM was developed is crucial to choosing an appropriate measure. Not infrequently, researchers choose questionnaires based simply on whether or not they have been "validated" and ask few questions about how the items for the questionnaire were constructed and tested. A poorly constructed or *ad hoc* questionnaire may be deemed "validated" simply because it has been used in various studies and some basic statistical evidence has been supplied. Frequent use of a questionnaire does not equate with quality nor improve its psychometric properties. Rather, to ensure that a PROM will ultimately prove to be a reliable, responsive, and valid measure, a rigorous step-by-step development process is essential. During the development process, careful qualitative work is necessary to conceptualize, map out, and operationalize the variables most relevant to patients. PROMs that are developed based on expert opinion alone cannot be expected to address all satisfaction and QoL issues that patients find relevant. Thus, while expert opinion is clearly valuable, patient interviews and focus groups are essential sources of information.

Since the early 1990s, there has been increasing international consensus regarding appropriate methods for the development and validation of QoL measures, culminating with the 2002 report by the Scientific Advisory Committee of the Medical Outcomes Trust⁶⁵ and more recently with the US Food and Drug Administration recommendations.⁶⁶ Cano *et al.*⁵¹ summarized these guidelines in a three-step approach to PRO measure development that involves procedures for item generation, item reduction, and psychometric evaluation. We have added a fourth step representing the ongoing process of instrument improvement (Fig. 10.9).

In the first step, the conceptual model to be measured is formally defined, and a pool of items is generated. These items for a PRO measure are developed through the following three sources: review of the literature, qualitative patient interviews, and expert opinion. The item pool is developed into a questionnaire which is pretested or pilot-tested on a small sample of patients in order to clarify ambiguities in item wording, confirm appropriateness, and determine acceptability and completion time.

In the second step, the PRO measure is field-tested using a large sample of patients. The questions that represent the best indicators of outcome are then retained in a shortened version of the PRO measure based on their performance against a standardized set of psychometric criteria. The research team's objective is to choose the best items from the field test measure for inclusion in the final measure. Items are eliminated according to tests of item redundancy, endorsement frequencies, missing data, factor analysis, and scaling assumptions. Acceptability, reliability, validity, and responsiveness are also

Fig. 10.9 Four steps of patient-reported outcome (PRO) measure development.

considered. The process completes questionnaire development and provides the first evidence of validation.

In the third step, further psychometric evaluation and validation is performed. This step involves the administration of the item-reduced questionnaire to a large population of patients to determine acceptability, reliability, validity, and responsiveness.

The fourth and final step involves the ongoing modification and improvement of the instrument. As an example, building upon the existing four modules of the BREAST-Q, a new procedure-specific module was recently developed for breast-conserving therapy (BCT) patients. This module facilitates comparisons between treatment groups (e.g., BCT versus mastectomy and reconstruction) and evaluations of new surgical approaches (e.g., oncoplastic surgery, fat grafting).

Our research group's development of the BREAST-Q illustrates how new PROM can be constructed. In phase I, a conceptual framework to understand patient satisfaction and QoL in breast surgery patients was developed and included six domains: satisfaction with breasts, overall outcome, and process of care, and psychosocial, physical, and sexual well-being. Our team developed this conceptual framework and set of items to measure each component of the framework using in-depth interviews and focus groups with patients, expert panels with plastic surgeons, and a review of the literature.⁶² We then performed pilot testing and cognitive debriefing to ensure that our PROM addressed all relevant issues and that the items were acceptable to patients and easily understood. In phase II, we performed an extensive multicenter field test with 1950 patients. Based on these data, item reduction and scale development were performed using modern psychometric methods. In this process, approximately 60% of the items were deleted. In phase III, the item-reduced measure

(BREAST-Q) was completed by another large sample of breast surgery patients and the data were examined to determine how the measure performed. More specifically, targeting, reliability, convergent validity, discriminant validity, and responsiveness were examined.⁶⁷

Modern psychometric methods

The science underpinning the testing of the attributes of reliability, validity, and responsiveness is known as psychometrics. The most commonly used form of scale evaluation, and the one most familiar to surgeons, is based on traditional psychometric methods.⁶⁵ However, in recent times, researchers have become aware of the limitations of these methods and are now moving to newer techniques. As such, modern psychometric methods such as Rasch measurement⁶⁸ and item response theory (IRT)⁶⁹ are increasingly being used in the development of PRO measures. Rasch and IRT methods were first developed for use in educational testing. While traditional psychometric techniques provide ordinal-level data, Rasch analysis provides interval-level data.⁶⁸ Ordinal-level data provides only a rank order (e.g., first, second, third). In contrast, with interval-level data, one unit on the scale represents the same magnitude measured across the whole range of the scale (e.g., degrees Celsius). This improves the accuracy with which we can measure clinical change. In addition, these methods provide estimates for patients (and items) that are independent of the sampling distribution of items (and patients). Among other benefits, this allows for accurate estimates suitable for individual-person measurement. This can help to inform patient monitoring, management, and treatment directly. Other advantages include item banking, scale equating, computerized scale administration, and the handling of missing data.^{70,71}

In the coming years, one may expect that these newer, more clinically amenable techniques will supersede traditional approaches to developing and testing PROM. Additionally in the near future, one may anticipate that electronic capture of PRO data will become widespread. As web access has become more prevalent throughout the world, it is possible for patients to complete questionnaires via the internet and even smartphones, which allow for real-time reports to both clinicians as well as patients.^{72,73} This has important implications for how PRO data may be used to inform clinical care. For research studies, the collection of ePRO data is also attractive as costs per patient are potentially reduced.

Utilities and preference-based measures

Key concepts

While PRO measures can provide valuable information on the way patients perceive their health and the impact treatments have on their QoL and other significant outcome variables, these measures do not incorporate patient preferences in their scoring systems.

“Preference” is a broad term used to describe the concept of desirability of a set of outcomes. Values and utilities are two different types of preferences, depending on which method is utilized to measure the preferences: values are measured under conditions of certainty (rating scale, time trade-off method), whereas utilities are measured under

conditions of uncertainty (standard gamble method).⁷⁴ Hence, a value or utility is a measure of preference for a particular health state or health service: the more preferable an outcome, the more value or utility is associated with it. The most common preference metric used is quality-adjusted life years (QALYs).

QALYs represent a measure of the dollar cost of a year of life if a person suffers one or more limitations of various kinds and degrees, taking into account both QoL and life expectancy.⁷⁵ QALYs can be estimated using a variety of evaluation tools such as the standard gamble, the time trade-off, or visual analog scales.^{75,76} Preference-based measures incorporate the strength of patients’ preference for the condition or disease, and the units of measurement range from 0.0 (i.e., death) to 1.0 (i.e., perfect health), the idea being that a year in perfect health is worth more to the patient than a year spent with a disability (Fig. 10.10). Importantly, some health states may be considered worse than death and thus have negative scores. Preference-based instruments thus take into account values and/or utilities in addition to QoL, and can be used in economic evaluations to aid resource allocation decisions.⁷⁷

There are two general approaches to measuring values and utilities. The first involves use of preference classification systems in which responses to a generic health status instrument are converted to a value or utility. This conversion is computed by an algorithm developed from population-based responses. Widely used preference classification systems include the Quality of Well-Being Scale,^{78,79} the McMaster Health Utilities Index,^{80–82} and EuroQol.^{83,84} Whereas preference classification systems are useful to study general health status and population health, they may not capture adequate

Fig. 10.10 Comparison of health states on a common utility scale. Utilities range from 0 to 1, where 0 represents death and 1 represents perfect health. Utilities differ from standard questionnaires in that they quantify quality of life with a single measure that encompasses the physical, psychological, and cultural preferences of the patient. This permits comparison between patients and across different diseases on a common scale.

Fig. 10.11 Utility assessment with the standard gamble technique. In standard gambles, patients are asked to make a choice between two alternatives. One alternative is to remain in their current health, and the other is to accept a gamble with a chance of success and failure. The chances of success and failure are varied systematically until the point of indifference between the two choices is reached. The probability of success at this point of indifference is the utility value. Typically, the worse the perceived health of the patient, the lower the utility.

information about specific conditions or individual patient preferences.

The second approach to measuring values and utilities is to assess them directly. Several techniques may be used, including a visual analog scale, time trade-off, and standard gamble.⁷⁶ The standard gamble is considered to adhere most closely to the von Neumann–Morganstern utility theory. In this technique, patients are asked to make a choice between two alternatives. One alternative is to remain in their current health state, and the other is to accept a gamble with a chance of success or failure (Fig. 10.11). The chances of success and failure are varied systematically until the point of indifference between the two choices is reached. The probability of success at this point of indifference represents the value or utility estimate. Typically, the worse the perceived health of the patient is, the lower the value or utility score (see Fig. 10.10). Whereas the concept of preference assessment holds great promise for plastic surgery,^{85,86} measurement of values and utilities is an evolving science. Controversy exists as to the gold-standard technique for measurement, and alternative techniques may give slightly different results.^{87,88}

Comparative effectiveness analysis

Definition

The primary purpose of comparative effectiveness research (CER) is to facilitate value-based medicine, which is the practice of medicine based on the value conferred by a healthcare intervention. Depending on the definition used, CER may or may not have a cost component in the analysis. There is no standard definition for CER and study design may vary depending on whose perspective is taken: patient, payer, societal.⁸⁹ The total value or utility gained is measured in QALYs and calculated by multiplying the years of utility gain by years of benefit duration. This total gain, or comparative effectiveness, can be compared with that of any healthcare intervention, no matter how disparate. The concept of CER in healthcare is similar to the consumer rating reports by Zagats for restaurants and consumer reports for cars.⁹⁰

There is currently no standard definition for CER. Most researchers use the following definition for comparative effectiveness by the Institute of Medicine: “Comparative effectiveness research is the generation and synthesis of

evidence that compares the benefits and harms of alternative methods to prevent, diagnose, treat and monitor a clinical condition, or to improve the delivery of care. The purpose of comparative effectiveness research is to assist consumers, clinicians, purchasers, and policy makers to make informed decisions that will improve healthcare at both the individual and population levels.”⁹¹ The analytic tools for data collection can include systematic reviews of evidence, modeling, retrospective analyses of databases, and prospective trials. Controversy surrounds the use of randomized controlled trials for CER because the research setting should demonstrate an intervention’s outcome under “real-world” situations rather than under optimal conditions (as demonstrated in Fig. 10.6).⁹⁰ However, the Institute of Medicine’s definition of CER does not reject the inclusion of randomized controlled trials.^{90,92}

National research priority

Reforming the national health system is a top priority for health policy leaders and the key aim is to control healthcare costs without impairing quality. Regional variations in treatment patterns and cost growth support the need for more informed medical decision-making.⁹² Many believe that this goal will only be reached if we have better evidence to inform healthcare decisions. Better evidence can improve quality, safety, and the effectiveness of healthcare by providing both patients and providers with the information needed to make healthcare choices.^{92,93} PCORI (Patient-Centered Outcomes Research Institute) was created in 2010 as an independent nongovernmental, nonprofit organization, to fund comparative clinical effectiveness research that addresses questions and concerns more relevant to patients.⁹⁴

Complexities

Whose perspective to take?

A variety of perspectives can be taken when examining the value of a healthcare procedure, ranging from the individual to society. The four most common perspectives evaluated are societal, patient, employer, and payer.⁹⁰ The societal perspective includes all of the benefits and costs associated with a treatment for the whole of society, rather than for just one individual patient. This type of analysis includes societal components such as work productivity and caregiver costs. The patient perspective only includes the costs and benefits of a treatment that impact the individual patient. Any increased productivity that would benefit a company or workplace situation would not be included. Productivity that directly benefited the individual would be counted. Costs included would be those paid out of pocket by the individual and costs related to travel and time off work.^{90,95}

An employer perspective only includes the benefits and costs of a treatment that impacts the employer. Any benefit from increased productivity by the employee is included. In addition, any tangential increased productivity is included, such as decreased sick leave from the other employees as a result of a vaccination. Costs included are out-of-pocket costs for the employer and lost productivity as a result of employee absenteeism.^{90,95}

The payer perspective includes the benefits and costs of a treatment that impact a payer only. Benefits to the individual

are not included. Increased productivity to the individual or society is not included. The time horizon used to calculate the benefits and costs is the expected length that the individual will participate in the insurance plan.^{90,95}

Types of economic studies

CER may or may not include cost when comparing treatments. However, there are five primary economic analyses in healthcare that compare treatments by costs and outcomes and differ primarily by how outcomes are measured. Firstly, cost-benefit analysis compares the net costs and net benefits of two treatments. Outcomes must be converted to monetary units, such as willingness to pay. The results are typically expressed as dollars expended for dollars gained.^{95,96} Secondly, cost-effectiveness analysis (CEA) measures the cost associated with two or more medical interventions for a given health state to determine the relative value of one intervention over the other. With CEA, the healthcare provider is looking to answer the following question: “What are the costs associated with the different treatment options available to achieve this goal?”⁷⁵ In a CEA, the health effects are measured in natural units directly related to the goal of interest associated with the intervention. For example, the measure of primary effectiveness can be expressed in terms of “cost per unit of effect”, where the effect can be the cost of life-years saved by kidney transplantation compared to dialysis,^{90,95,96} the average blood pressure decrease in mmHg, or the number of successful replantations.⁹⁷ Thirdly, cost-utility analysis (CUA) was developed to address the limitations of CEA. It has emerged in recent years as the preferred method for economic evaluations in healthcare because both the QoL and length of life must be assessed.^{75,90,95-98} Overall, CUA and CEA share similarities from the cost analysis perspective. However, they differ in terms of outcomes: in CEA, outcomes are single and specific to the medical intervention under study; in CUA, outcomes can be single or multiple, and, most importantly, consider the notion of preference.⁷⁴ The analysis produces a cost per QALY for the intervention that can be compared to other procedures. Fourthly, cost consequence analysis does not convert outcomes to a common metric but instead lists all of the consequences of the treatment.^{90,95} Lastly, cost minimization analysis is used to compare the costs of procedures when the outcomes are identical. This approach is rarely performed because two procedures usually have something different in regard to issues such as complication rates, pain, and time of recovery.^{90,95,96}

A controversial issue is whether costs are appropriate outcomes in CER. The primary justification for including costs is that the overall value of an intervention can be easily understood in economic terms.⁹² However, CER may conclude that the more expensive treatment has the best value. An example is breast cancer screening in patients with *BRCA* genetic mutations. In a study by Plevritis *et al.*, magnetic resonance imaging screening was found to be cost-effective relative to mammography.⁹⁹ CER looks at the benefits, not just the costs, and therefore identifies the treatment with the best value, not necessarily the one with the lowest cost.⁹² A cost-effectiveness analysis in breast reconstruction used the BREAST-Q as the effectiveness measure to analyze whether implants or autologous reconstructions were more cost-effective from the payer perspective. Autologous

reconstruction, all things considered, was a cost-effective option compared to implants when the expected lifespan of a patient was long (i.e., young women or early-stage breast cancer).¹⁰⁰

Study design

As previously discussed, there are two broad categories of research design: experimental and observational studies. Observational research has many advantages, such as speed, real-world decision, large sample sizes, and low cost. Experimental studies, such as randomized clinical trials, can overcome some of the limitations of observational studies by randomly assigning patients to different interventions, thereby controlling for known and unknown confounding factors. The Institute of Medicine’s recommendations are for the national CER program to develop large-scale, clinical and administrative data networks to facilitate the use of observational and experimental data to inform CER.⁹³

Limitations

There are several potential limitations to the implementation of CER in healthcare. For one, there is no standard definition for comparative effectiveness. It is also unclear what impact this type of research will have on healthcare since many providers do not incorporate this type of information into medical decision-making. Population-based study results may not be applicable to individual patient needs. For example, autologous breast reconstruction may be cost-effective compared to implants but the final decision of the method of breast reconstruction needs to be made by the patient. Patient treatment self-selection may also affect comparative effectiveness results. A study that finds no statistically significant difference in treatment outcomes does not necessarily mean that there is no difference in outcomes. The lack of statistical significance may be due to flaws in the study design, such as an underpowered study. Furthermore, different perspectives such as societal, patient, and employer may have different results. It is important to understand that CER helps to inform a medical decision but does not provide a simple “one size fits all” answer.⁹⁰

Summary

The primary reason for the interest by patients, providers, and health policy leaders in CER is the belief that better information will translate into better decisions and improved health outcomes. The long-term impact of these efforts will depend on healthcare reform legislation, the medical profession’s ability to encourage physicians to change practices, and patients’ willingness to participate in shared medical decision-making.⁹³

Future trends

Multicenter clinical trials network

When choosing a treatment option for their patients, plastic surgeons use many sources of information to determine best practice. Understandably, surgeons tend to rely in large part on their training and personal experience. Outcome studies

reporting “single-surgeon experience” have traditionally predominated in the plastic surgery literature. While such series are of value, their findings are not necessarily generalizable to other settings (e.g., lower-volume practices).

One of the more powerful forces in shaping best practice is the randomized clinical trial. However, in certain settings, single-center trials may be difficult to conduct because of limitations in sample size and resources. One way of preserving the clinical relevance of a trial is to have multiple institutions enroll, treat, and follow patients under a common study protocol. This approach also increases the heterogeneity of the population, which may ultimately lead to study findings that are more generalizable and relevant. This heterogeneity may however make it more difficult to detect treatment differences. Compared to a single-center trial, a treatment effect may be more difficult to detect in a multicenter trial. However, those effects that are detected are likely to be more convincing than those found in a single, homogeneous population.

To facilitate such studies, the Plastic Surgery Education Foundation established the Clinical Trials Network. This initiative has provided a mechanism by which plastic surgeons across the country may collaborate and contribute to the advancement of clinical knowledge. One compelling example of the value of multicenter clinical trials in plastic surgery is the Venous Thromboembolism Prevention Study. In this study, performed under the direction of the Network, five high-volume plastic surgery centers have adopted a common protocol for perioperative chemoprophylaxis of deep venous thrombosis. The incidence of venous thromboembolism is being prospectively evaluated and will be compared with the incidence of events occurring in a retrospective cohort of patients who did not receive prophylaxis. Data from this study will inform national recommendations for chemoprophylaxis, support the practice of evidence-based medicine and, ultimately, improve patient safety. One important barrier to multicenter trials in plastic surgery is the cost. Multicenter registries may be a more “cost-effective” form to evaluate outcomes and measure quality.

Knowledge translation

As clinical research in plastic surgery continues to advance rapidly, information overload is a constant challenge for surgeons. Incorporation of research findings into plastic surgery practice currently relies on publications in peer-reviewed journals and educational activities such as continuing medical education (CME) and continuing professional development (CPD). Because of their passive nature, CME and CPD have had limited effects on modifying physicians’ practice. Discrepancies or care gaps remain between what is recognized as evidence-based practice and the care provided in everyday plastic surgery practice. Moreover, patients may be receiving potentially harmful or unproven medical and surgical interventions. In a 2001 report entitled, *Crossing the Quality Chasm: A New Health System for the 21st Century*,¹⁰¹ the Institute of Medicine identified three main gaps in quality of care: medical error, overuse, and underuse. As an example, despite evidence that the risk of deep venous thrombosis is particularly high for patients undergoing combined abdominoplasty and liposuction, only 60% of plastic surgeons report use of thromboprophylaxis all the time.¹⁰²

The Canadian Institutes for Health Research (CIHR) is responsible for coining the relatively new term “knowledge translation” (KT) and defines it as “a dynamic and iterative process that includes synthesis, dissemination, exchange and ethically sound application of knowledge to improve the health, provide more effective health services and products and strengthen the health care system.”¹⁰³ KT has been proposed as a solution to reduce care gaps, ensuring collaboration between the public, patients, clinicians, managers, and policy-makers to inform health-related policy and practice.^{104,105}

A model for understanding KT

The CIHR elaborated a Knowledge To Action model, further subdividing KT into two categories: (1) end-of-grant KT and (2) integrated KT.^{104,106} In end-of-grant KT, strategies are developed to match research findings to the needs of the appropriate individuals and organizations after research activity is completed. This approach is also known as diffusion and dissemination of research findings. Conversely, integrated KT engages individuals and organizations in every step of the research process, from establishing the research question to interpretation and dissemination of the findings. The goal of this approach is to produce research findings that are more likely to be relevant to, and used by, the stakeholders, including patients, clinicians, managers, and policy-makers.^{107,108}

A variety of models exist to improve quality of healthcare through KT. One of the most common is the 4T model. The first strategy, referred to as T1 (translation 1), focuses on transforming basic science findings into translational research. Next, T2 (translation 2) comprises all activities directed at producing clinical studies based on translational research findings. Activities under T3 (translation 3) center on the dissemination and delivery of healthcare interventions to all patients, in every setting of care. Finally, T4 (translation 4) activities focus on translating dissemination experiences into new basic science investigations.

Barriers to uptake

The healthcare system currently falls short in its ability to translate knowledge into clinical practice. A study comparing medical care in the US with established national guidelines, medical literature, and existing indicators of quality demonstrated that, overall, patients received 54.9% of recommended care.¹⁰⁹ In fact, it takes an average of 17 years for new knowledge generated by research, such as randomized controlled trials, to be integrated into widespread practice.^{110,111} In a systematic review of the literature by Cabana *et al.*, the sequence of behavior change in a physician’s clinical practice has been divided into three domains: knowledge, attitude, and behavior.¹¹² Each domain may encounter opposing forces to the application of evidence-based knowledge. Firstly, physician knowledge acquisition may encounter barriers such as lack of familiarity and lack of awareness (e.g., increasing volume of new literature, time invested to stay informed). Secondly, physician attitudes that favor behavior change may be deterred by the lack of outcome expectancy, self-efficacy, and motivation (e.g., mistrust regarding the validity of clinical research, skepticism about the applicability of evidence to clinical practice, discomfort regarding modification of previous practice). Lastly, factors hindering the practical

application of behavior change reflecting new research-based knowledge may be external (e.g., patient refusal, conflicting research evidence, lack of resources, organizational constraints).^{112,113} Other factors influencing successful implementation of evidence-based interventions include miscommunication between the organization and the healthcare providers, preventing identification of factors hindering compliance with recommended practices. Successful implementation of evidence-based practice has thus far depended on the adoption of a comprehensive program that incorporates methods to improve culture, teamwork, and communication.^{114,115} There is now a burgeoning field called the science of healthcare delivery.^{116–118}

Learning collaboratives

In a quest to improve healthcare delivery, the Institute for Healthcare Improvement developed a learning collaborative model in 1995, called the Breakthrough Series model. It is an ongoing learning process in which groups of practitioners from different healthcare organizations work in a structured environment to improve a chosen area of their practice.¹¹⁹

While clinical trials networks are designed to test an intervention (e.g., drug, surgical procedure, medical device, screening approach), quality improvement learning collaboratives focus on the best way to adopt, implement, and adapt evidence-based practice to real-life environments. These collaboratives often identify ways to improve quality and reliability and to decrease healthcare costs by meticulous comparisons of variation in care processes, culture, and systems between organizations.¹²⁰ Many successful collaboratives have come together around diverse health conditions such as cardiac care,¹²¹ cystic fibrosis,¹²² infant care,¹²³ central line infection,¹¹⁴ and a whole host of topics sponsored by the Institute for Healthcare Improvement.¹²⁴

In collaborative endeavors, the ultimate goal is to promote the dissemination and adoption of evidence-based practice to help organizations and healthcare professionals close the gap between actual and best practice in healthcare. Using adult learning principles, learning collaboratives allow practitioners to collaborate and learn from their collective experience and challenges. By bridging together practitioners with different roles in the same organization¹¹⁴ and from different organizations,¹²⁵ information is shared on best practices, quality methods, and experiences while implementing systematic improvements to the overall system of care.

In their systematic review, Schouten *et al.*¹²⁶ reported on the impact of quality improvement collaboratives, and concluded that the evidence is “positive but limited” and that further study is warranted to understand the most effective models. Hospitals or providers with worse outcomes could learn best practices of those with better outcomes. An example of this is the Michigan regional collaborative improvement program, funded by a private insurance carrier, that decreased surgically related complications in general, and vascular surgery in particular by 2.6% (2500 patients) with savings of approximately \$20 million.¹²⁷

What does this mean for plastic surgeons? Within plastic surgery, a pilot learning collaborative has been launched using TOPS as a central data repository.¹²⁸ The collaborative’s focus is on sharing practices around abdominal procedures and resultant seroma rates. A challenge for the plastic

surgery community is that a high percentage of surgeons practice alone in a private practice setting and may lack the resources needed to participate in such endeavors. In addition, the practice of plastic surgery takes place in a highly competitive marketplace where a culture of collaboration, rather than competition, may be a difficult, but not impossible, shift to enable. It is possible that outside forces such as changing reimbursement strategies will nudge our community towards recognizing the value in collaborative learning and improvement.

Role of electronic medical records/ integrating data collection into flow of usual care versus research

To have truly effective KT and continuous improvement in the quality, safety, and value of healthcare, an infrastructure that supports data use in clinically intelligent ways is paramount. Current systems are limited by use of paper and by lack of interoperability, even when electronic data are available, thus making the majority of clinical data relatively inaccessible in practical terms. Where clinical data are currently used, e.g., Surgical Care Improvement Project (SCIP)¹²⁹ measures and National Surgical Quality Improvement Program (NSQIP)¹³⁰, full-time employees must be hired to abstract data manually from paper or electronic records and re-enter them in a different format for submission. Due to these high labor costs, only a small sample of surgical cases and data points can be included. When clinical research trials are performed, much of the data collection is done on paper, duplicating information already present in the medical record, which again represents a very labor-intensive process. Furthermore, when patient-reported data are collected, patients may be asked to answer questions similar to those already asked during the clinical encounter, thus adding significant redundancy to patients as well. In addition, it can be challenging or even impossible to score paper-based questionnaires at the bedside, thus depriving the patient-provider relationship of data that could otherwise have a significant impact on their decision-making.

Several specialty societies, including the American Society of Plastic Surgeons, have hired consultants to design data collection websites such as TOPS. However, this typically requires practitioners to abstract data manually and re-enter it into the national database, thus creating a significant barrier to participation by many. Few groups, other than the Cancer Trialists Collaborative Group, which receives national funding, have been successful at carrying out and sustaining such efforts.

Possible solutions: generic

With the evolution of computer technology and the internet, the feasibility of turning data into meaningful information for activities such as decision-making at the bedside, physician feedback, benchmarking, improvement of care, credentialing, certification, and research is becoming much more affordable, practical, and realistic. Although information technology has much to offer in enabling the transformation of healthcare delivery, it has been slow in adoption and effectiveness compared to other industries. To stimulate growth, the federal

government has developed a 5-year plan to phase in and define “meaningful use” of electronic medical records (EMRs).^{131,132} The hope is that this will increase meaningful adoption of health information technology (HIT) by both providers and hospitals. The Medicare and Medicaid incentive program will provide incentive payments to hospitals or providers that implement, upgrade or demonstrate EMR technology. There is a three-stage plan for implementing the meaningful use of EMR from 2011 to 2016: data capture and sharing, advance clinical processes, and improved outcomes.¹³²

Standards for PROMs have not yet been included in the current and future proposed definitions of “meaningful use”. However, decision support rules and best practice alerts may well benefit from inclusion of these measures. For instance, a PRO instrument for depression could generate a best-practice alert for referral to a mental health professional.¹³³ Likewise, a PRO measure for domestic abuse could generate a best-practice alert for referral to social services professionals. Having such PRO measures integrated into the flow of care electronically, thus enabling immediate scoring and reporting to the healthcare team, advances our ability to provide high-quality care. This reaches beyond what we have been able to achieve in the past with paper-based and research measures administered and scored well after an office encounter, and often never reported back to the care team. For example, the International Consortium of Health Outcomes Measurement is a nonprofit organization that aims to transform healthcare by standardizing the way to measure outcomes. Their recommendations for measuring the value of care for individuals with cleft lip and palate include 9 dimensions of outcomes, four of which are captured with CleftQ.¹³⁴

The gradual adoption of EMRs by more and more health systems, practices, and individual practitioners provides a growing opportunity to capture structured data at the point of care. Not only can these systems facilitate the systematic capture of data, but they also allow systematic analysis and reporting. This reporting can be done with several purposes in mind, such as instantly providing decision support and best-practice evidence to providers at the time of patient encounter. The reporting can be “rolled” up to a cohort of patients with similar health conditions (e.g., all breast cancer patients), similar procedures (e.g., all free flaps), or on a provider’s panel (e.g., all surgical cases performed by the same surgeon). These reports could also be aggregated at the practice level, departmental level, or at the national level.

Possible solutions: plastic surgery and PROMs

It is often a challenge for plastic surgeons to mobilize the resources within their clinical environment to develop and program the tools to collect field-defined data specific to the specialty. However, several innovative centers have begun to do just that with PROM. Just as we have easy access to timely and standardized laboratory results, so should we have similar availability of timely and standardized PRO at the bedside. In many cases, particularly in the specialty of plastic surgery, PROM may provide us with better decision-making information, or may add an important dimension to more traditional biometric measures. For instance, the Levine score¹³⁵ for carpal tunnel patients, when available during an encounter, is very helpful to individual patients and their surgeons in quantifying the impact of the symptoms and in

tracking the effect of a particular treatment. Likewise, the BREAST-Q⁶² has been developed to provide useful bedside information as well as valuable research information.

At Dartmouth, we have been able to integrate electronic patient-reported intake and outcomes into routine care for the purpose of improving the quality and efficiency of care, reporting, and research. This has been operationalized across 30 clinical conditions including comprehensive breast care (BREAST-Q) and hand care (Quick Disabilities of Arm, Shoulder and Hand, Boston Carpal Tunnel Questionnaire). At Memorial Sloan-Kettering, the BREAST-Q is routinely administered at the point of care allowing for the clinical use of this information and implementation of interventions when needed. Plastic surgeons participating in TOPS can sign up to have the BREAST-Q sent to their breast patients for longitudinal postoperative tracking. A common sentiment expressed by practitioners who have access to these measures at the time of an encounter is that they cannot imagine ever returning to a practice style where this information was not available.

As we become more sophisticated at measurement, it becomes important that, as a community, we endorse and use the same measurement tools so that we can make meaningful comparison of the data through our national registry. There is no doubt that these measures will continue to improve through an ongoing iterative process. The more plastic surgeons participate, the more they can help shape the design of these data systems to make them even more practical at the bedside, and more effective at answering important clinical questions through well-designed research studies and learning collaboratives. The ICHOM (International Consortium for Health Outcomes Measurements)¹³⁴ organizes groups of physicians, researchers and patient advocates to define a standard set of outcomes measures, advocating for global adoption so providers can compare, learn and improve. This may promote international collaboration and decrease healthcare costs. Currently, they have 12 completed datasets (including cleft palate) but aim to have 50 by 2017.

What do we do with the outcomes?

EMRs and HIT have the potential to improve the quality of healthcare and support the transformation of the way medicine is practiced and provided to patients. Computerized continuous quality assessment from data found in EMRs should facilitate ongoing monitoring and improvement of healthcare quality as well as clinical decision-making. Numerous national initiatives are currently assessing ways to measure care systems with the goal of collecting and comparing data on the structure of healthcare systems, care interventions, and patient outcomes. These data are valuable to many stakeholders: patients, providers, healthcare payers, and government agencies. Thus, there is currently an unprecedented focus on quantifying healthcare value, because improving the outcomes of care at a more affordable price is an important and pressing challenge.

The first model summarizing factors influencing patient outcomes was developed by Donabedian in 1966.¹³⁶ This framework is still relevant today, and hypothesizes that care structures (e.g., dedicated microsurgical care team) and care processes (e.g., standard limb replantation care pathway) play

a role in patient outcomes. In this type of model, outcomes can take any form appropriate to one's practice: for example, mortality, health status, functional status, satisfaction, QoL, and cost.

The creation of clinical practice guidelines has become a strategy frequently used to improve healthcare quality and outcomes. They represent a way of outlining evidence-based practices through a review and synthesis of the literature in an attempt to guide patient care better. However, although extremely useful, guidelines alone are not sufficient to produce improvements in the quality of care. The strategy of publication and dissemination of practice guidelines has failed to guarantee their implementation, and there may be physician resistance as clinicians feel their autonomy is compromised. Also, clinical guidelines do not account for patient variability, but need to be updated very often since medical knowledge is continually changing. An alternative to clinical guidelines is standardized clinical assessment and management plans (SCAMPS): flexible and continuously improving care guidelines created by physicians, with the aims of decreasing practice variability, optimizing use of healthcare resources and improving patient care. SCAMPs allow physicians to adapt clinical pathways to individual patient needs by incorporating current scientific evidence but also including patient characteristics into the pathway. Since 2009, more than 12 000 patients have been enrolled in 49 adult and pediatric SCAMPs in nineteen institutions, with reduction of practice variability and improved patient outcomes.¹³⁷

Performance measures

In the process of facilitating the measurement of healthcare quality, performance improvement measures serve as a vehicle for translating the strongest clinical evidence into practice more rapidly. Measures typically go through many iterations before they are widely endorsed as being meaningful and reliable. In the earlier stages of maturation, it has been proposed that the measures be called "quality metrics".¹³⁸ These metrics can be used to assist providers, hospitals, or the healthcare system in self-assessment, enhancing both the quality of care and patient outcomes. With repeated improvements in the measures themselves, they may rise to the exacting standards of organizations such as the National Quality Forum¹³⁹ and be endorsed as formal "performance metrics"¹³⁸ and used for public reporting, comparison of care between institutions or healthcare providers, P4P initiatives, and for meaningful use initiatives. The credentialing and financial incentives behind compliance with performance metrics encourage healthcare providers and organizations to offer the strongest evidence-based quality of care.

One of the main examples of a process-driven quality initiative is SCIP.^{129,140,141} This national quality partnership of organizations was initially a voluntary collaborative to improve surgical care by reducing surgical complications. It transitioned to a mandatory, publicly reported system in 2005.¹⁴² The ultimate goal of this program was to reduce the incidence of preventable surgical morbidity and mortality nationally by 25% by the year 2010 through collaborative efforts. This program has four preventable complication modules: (1) surgical site infections;¹²⁹ (2) venous thromboembolism;¹⁴³ (3) cardiovascular events; and (4) respiratory

complications. The withholding of a pro-rated Medicare payment was used as a financial incentive to guarantee participation in SCIP. However, at present, studies evaluating the effect of SCIP process measures following colorectal surgery on surgical site infection rates have mixed results.^{144,145} Of note, these studies have relatively small sample size at each participating institution. Furthermore, SCIP measures of performance target a limited set of surgical procedures, none of which pertains to plastic surgery. Such measures are primarily useful at the organizational level, but not at the level of the individual provider. However, collection of SCIP measures from a data-rich EMR will make reporting at the individual provider level much more feasible.

The American College of Surgeons' National Surgical Quality Improvement Program (NSQIP)¹³⁰ is another initiative that is gaining increased traction amongst surgical specialties and hospitals to track and improve surgical outcomes. For participating hospitals, and the surgeons they represent, clinical data rather than administrative data can be used to compare outcomes across organizations and support improvement efforts. One of the flaws is that outcomes are reported only for the first 30 days, leaving insufficient time to analyze outcomes in some plastic surgery procedures.¹⁴⁶

To date, two studies addressing performance measures in plastic surgery have been conducted in the UK. The British Association of Plastic Surgeons, following a requirement of National Health Service clinicians to take part in clinical audits, has taken the initiative to identify surgical procedures that could be used as markers of performance across the specialty.¹⁴⁷ In their pilot study, a national performance assessment for pedicled and free-flap survival was completed. When comparing four plastic surgery units, the overall outcome achieved was 89% total flap survival. In 2011, the National Mastectomy and Breast Reconstruction Audit reported outcomes in more than 8000 women with mastectomy and reconstruction in the UK. The Breast-Q was chosen as one of the outcome measures. This study was useful to determine benchmarks, analyze level of satisfaction in patients with breast reconstruction, and identify providers with better and worse outcomes, amongst others.¹⁴⁸ The multicentre MROC study (Mastectomy Reconstruction Outcomes Consortium) is currently enrolling patients in 11 centers in the US, and it was designed to explore patients' experiences after reconstruction regarding aspects such as satisfaction with breasts, psychosocial well-being, postoperative pain, etc. Patient questionnaires are administered at several points (preoperative, one week, three months, one year and eighteen months), and the study is projected to close accrual in 2016. This important study will shed light on the patient's point of view regarding breast reconstruction method, timing, but also costs with the different procedures.¹⁴⁹

The Maintenance of Certification Program of the American Board of Plastic Surgery has ventured into this arena of physician performance measurement. Their Practice Assessment in Plastic Surgery (PA-PS) modules include 20 of the most common plastic surgical procedures. Some data analysis from this system has already found use.¹⁵⁰ Although far from being as robust as what will be needed in the future, these modules will likely undergo frequent upgrades to improve their usefulness to the practicing clinician and will undoubtedly include PRO in the future.

On another front, the Joint Commission that accredits healthcare organizations has created a standard around evaluation of professional practice at the individual provider level.¹⁵¹ Like other initiatives, preliminary measures will be derived largely from process data and perhaps surgical complications and we will await future iterations to integrate patient-reported outcomes.

Public reporting and P4P

Despite limited evidence on their benefits, public reporting of hospital quality data and P4P are the two most advocated strategies to accelerate improvements in healthcare quality and safety.¹⁵² Measuring and publishing information about quality of hospitals, health plans, and physicians are driving P4P programs. Public accountability of quality measures has proved an excellent motivator for healthcare providers and hospitals to invest efforts in quality activities, as performance measures are open to the public for review.^{153,154}

P4P is a compensation model used by private payers that links financial incentives to the quality of healthcare provided.¹⁵⁵ While the P4P concept is gaining momentum as a means of improving overall quality of care by reducing gaps between clinical practice and evidence-based guidelines, it is also viewed as a way of encouraging efficient use of healthcare resources. P4P initiatives can take various forms, encompassing different payment models, various stakeholders (e.g., hospitals, group practices, private practitioners), and diverse clinical conditions. The available evidence regarding the impacts of P4P has been mixed.^{156–158} Some large-scale studies report moderate enhancements in process-of-care measures, but to date, no impact has been reported on patient outcomes or efficiency of care.^{152,159–161} Pay for performance (value-based purchasing) is an important part of the Affordable Care Act, intended to financially incentivize hospital/provider performance. Scores reflect achievement compared to other hospitals, as well as yearly improvement. Value-based incentive payments will be given to providers who deliver higher-value care (e.g., fewer complications) and meet certain performance standards, as evaluated by different outcomes measures.¹⁶² Additionally, the US federal government has introduced its own Pay for Reporting (P4R) program: the Physician Quality Reporting Initiative. This initiative offers financial incentives to Medicare providers who participate in quality reporting. Unlike P4P programs, the P4R model compensates physicians regardless of their performance on process and outcome measures.¹⁶³

In 2002 and 2003, a natural experiment occurred, involving thousands of American hospitals participating in a national public reporting initiative, with more than 200 organizations engaged in a simultaneous P4P initiative. Lindenauer *et al.*¹⁵² observed that hospitals participating in both public reporting and P4P programs showed modestly greater improvements in healthcare quality than hospitals engaged in public reporting alone.

Some critics argue that little evidence links performance measures to patient outcomes.¹⁵⁴ One explanation for this may be found in the realization that current measures focus on a very small number of processes of care out of the total interventions that characterize the patient's experience in the hospital.¹⁵³ Also, results of randomized controlled trials with

homogeneous study samples may not be generalizable to all patients.¹⁵⁴ Besides, outcomes in daily practice are influenced by various amalgamations of patient and treatment variables, which are seldom replicable in randomized controlled trials. In addition, many of the studies that failed to demonstrate an improvement in outcomes did not assess outcomes occurring at longer intervals after the delivery of the process of care to the patient. Moreover, the present burden of comprehensive data collection limits investigators' ability to capture patient information between care settings over time. Data collection should be facilitated by the widespread use of electronic medical records, allowing researchers to evaluate long-term outcomes readily.¹⁵³

Decision aids for patients

Making an informed decision about the best treatment can be difficult for patients, especially when there is more than one medically reasonable option. Over the last 30 years, the field of evidence-based decision-making in healthcare has grown rapidly. Patient decision aids aim to support this process and help patients arrive at informed value-based choices. According to the International Patient Decision Aids Standards collaboration, decision aids are evidence-based tools designed to prepare patients to contribute actively to the decision-making process when choosing among healthcare options, according to their preferences and values.^{164–166} They differ from conventional patient education materials in that they are more detailed, specific, and deliberated, and they provide a more personalized focus on options and outcomes, with the goal of helping patients make informed choices. Decision aids for patients do not replace the patient–physician encounter; instead, they supplement the provider's counseling about healthcare options.¹⁶⁴ They can be used before, during, or after an interaction with a practitioner.

A recent Cochrane systematic review of patient decision aids reported that they improve patients' knowledge regarding their options, and reduce decisional conflicts from feeling uninformed or confused about personal values.¹⁶⁴ After using decision aids, fewer patients are ambivalent about their treatment choice. Importantly, more patients participate actively in the decision process. However, randomized controlled trials have failed to demonstrate that these tools improve patient outcomes such as decision uncertainty, satisfaction, anxiety, or QoL.¹⁶⁷ Moreover, there is scarce evidence on the effects of decision aids on patient compliance with treatment, decisional regret, litigation rates, healthcare costs, and resource use.¹⁶⁴

Evidence supporting the use of decision aids in clinical practice is substantial.^{164,167,168} A good decision aid should meet the needs of its target population, and be acceptable to both patients and providers who wish to incorporate them in their clinical practice. Barriers to successful implementation are the lack of effective systems for delivering decision support. Further research is needed to assess the effects of decision aids on congruence between patients' values and their chosen options.

Designing and building high-quality decision aids is greatly enhanced when the available evidence base, including patient-reported outcomes, is robust. There is much opportunity for the plastic surgery community to add to this evidence base.

Conclusions

This chapter would be incomplete without emphasizing the key take-home messages. A clinician cannot make good decisions without good evidence and cannot generate good evidence without good study design and good data. Maximizing patient care and surgical outcomes will require continuous efforts to identify information needs and to produce the best evidence to fulfill these needs. Outcomes research offers a broad spectrum of methods by which to obtain good evidence, and these have been insufficiently leveraged by our specialty. In particular, measuring the patients' perspective on outcomes is a crucial dimension of research and clinical

care that is underdeveloped and underutilized. Measuring outcomes is not just about the final result of our interventions but a means by which we gather evidence to improve decision-making, the processes of care, and the systems in which we work. Collaborative data collection through clinical trials and quality improvement initiatives is essential to the generation of clinically meaningful information in our specialty. Our decisions need to be based on the highest-quality evidence and not the accumulated experience of a single surgeon, even if that surgeon is truly expert in the field. Equally important to generating clinically meaningful information is to translate that information into practice by providing surgeons with mechanisms to implement and monitor new standards.

11. Walach H, Falkenberg T, Fonnebo V, et al. Circular instead of hierarchical: methodological principles for the evaluation of complex interventions. *BMC Med Res Methodol*. 2006;6:29. Walach and co-authors discuss the widely held assumption around the hierarchy of evidence which places randomized controlled trials (RCTs) at the top – which are in turn trumped only by meta-analyses of multiple RCTs. However, this hierarchy is based on a pharmacological model of therapy. When generalized to other interventions such as integrative medical management, wound healing, and surgery, the hierarchical model is valid for limited questions of efficacy. RCTs are strong in the arena of internal validity (minimization of bias), but not as much so in regard to external validity or generalizability of the findings. Rather than an “evidence hierarchy”, they propose a “circular model” of evidence that would include multiple methods, with different research designs, balancing strengths and weaknesses to arrive at the best clinical evidence.

Principles of cancer management

Evan Matros, Tomer Avraham, and Babak J. Mehrara

SYNOPSIS

- There has been a gradual progression from radical to more conservative resections of many cancers.
- Neoadjuvant therapies have facilitated resectability and even down-staging of some tumors.
- A better understanding of immunology has led to the development of biologic therapies.
- Targeted therapies represent a new paradigm in the treatment of cancer aiming to combine efficacy and decreased toxicity.
- Rational, evidenced approaches to tumor ablation should aim to improve oncologic outcomes, reduce morbidity, and facilitate reconstruction.

Background

The introduction of reconstruction after extirpation was a major advance in cancer management. Plastic surgical techniques have facilitated large-scale resections by enabling immediate closure of surgical defects. Furthermore, development of microsurgical techniques enabled transfer of highly vascularized flaps from distant donor sites, thereby increasing the versatility of the reconstructive techniques and obviating the need for time-consuming surgical delay procedures or waltzing flaps.

Improved understanding of tumor pathobiology and prognostic factors has led to a gradual paradigm shift in cancer treatment from a “one size fits all” approach to tailored oncologic therapy. This chapter provides background for the current rationale behind modern treatment of tumors.

History of cancer treatment

While surgery remains the most successful single modality treatment for solid tumors, the past century has demonstrated an increased role for multimodality therapy. The goal of

current treatment for solid tumors is to minimize the deformity of wide-scale surgical extirpation, with assistance of neoadjuvant and adjuvant chemoradiation, to provide the greatest likelihood for cure.

Neoadjuvant treatment is the term used to describe either chemotherapy and/or radiation that are administered prior to tumor excision. Neoadjuvant therapy is used to shrink unresectable tumors rendering them resectable, or to decrease the magnitude of the ablation necessary to achieve negative margins.¹ Patients may undergo a complete response with total preoperative tumor eradication, or a partial response to neoadjuvant therapy. The response to neoadjuvant chemotherapy is an important predictor of outcome and can determine which chemotherapy is used postoperatively.² Clinically neoadjuvant therapy is a common part of treatment algorithms for many solid tumors. For example, randomized trials demonstrate lower recurrence rates for T3 and T4 rectal tumors when chemoradiation is delivered preoperatively as compared to postoperatively.³ Furthermore, for distal tumors lying near the anus, neoadjuvant therapy facilitates sphincter preservation by converting cases that potentially require abdominoperineal resection to low anterior resections.⁴

Neoadjuvant chemotherapy has come to play a significant role in the management of breast cancer, with significant impact on reconstructive decision-making for the plastic surgeon. Traditional indications for neoadjuvant chemotherapy include large tumor size, N2 nodal status, and inflammatory component. More recently it has been advocated for tumor down-staging and to facilitate breast conservation.⁵ Increased use of neoadjuvant therapy in breast cancer has resulted in recognition of pathologic complete response, whereas no tumor is identified on surgical specimen following completion of chemotherapy. Further study is required to determine if the need for ablative surgery is obviated in this setting.⁶

Disadvantages of neoadjuvant therapy include the possibility for disease progression prior to surgical resection and increased rates of surgical complications due to side effects of chemoradiotherapy. For example, in a review of nearly 1200

Fig. 11.1 Superiority of lesser resections to radical surgery. **(A)** This patient had a less aggressive surgical approach with a nipple-sparing mastectomy followed by immediate autologous tissue reconstruction. **(B)** The second patient had a more aggressive modified radical mastectomy, followed by radiation and delayed reconstruction. Note that while both patients have acceptably cosmetic reconstruction, the outcome of the patient shown in (B) is inferior to that of the patient shown in (A). In part due to the extensive nature of her surgery, she has more extensive and noticeable scarring, as well as skin color mismatch.

microsurgical breast reconstructions, Mehrara *et al.* demonstrated that neoadjuvant chemotherapy was an independent risk factor for postoperative complications in breast cancer patients undergoing microvascular breast reconstruction resulting in increased rates of wound complications if surgery was performed less than 6 weeks after completion of chemotherapy.⁷

In the adjuvant or postablative setting, chemotherapy or radiation is implemented to decrease locoregional recurrence or systemic disease by treating microscopic tumor deposits or metastases that are not detectable at the time of surgery. It is important to emphasize, however, that even if radiation or chemotherapy is planned postoperatively, all attempts should be made (if surgically feasible) to obtain microscopically negative tumor margins at the time of surgical resection. This concept is based on the fact that negative tumor margins are an important predictor of local or regional metastases in most solid tumors.⁸

Surgery

The earliest treatment for tumors was fulguration using electrocautery, application of toxic materials, or surgical extirpation. Due to the high local recurrence rates seen after tumor excision, surgical management at the turn of the 20th century developed into a “bigger is better” approach with wide margins. The best-known example is the Halsted radical mastectomy for invasive breast cancer advocating the removal of the pectoralis major muscle, all of the breast tissue and axillary nodes.⁹ Similarly, head and neck malignancies were treated with internal jugular vein ligation, sternocleidomastoid muscle resection, and spinal accessory nerve sacrifice. Such aggressive approaches to tumor control have subsequently been shown to be unnecessary for many cancers. Instead, the efficacy of limited anatomic resections has been proven in studies which: (1) demonstrate equivalency with more radical approaches, or (2) combine surgery with multimodality therapy. For example, margins greater than 2 cm have shown no benefit in the treatment of cutaneous melanoma.¹⁰ Additionally, effective treatment of breast cancer no longer mandates mastectomy if lumpectomy is combined with postoperative radiotherapy.¹¹ Nipple areola-sparing mastectomy would have at some time been considered

unthinkable and today is being utilized with ever increasing indications. Modern surgical therapy uses insight gained from clinical trials to minimize the scope of resection with an eye on preserving form and function (Fig. 11.1). Radical approaches are reserved for only the most advanced cancers with extensive local invasion.

While the utility of primary tumor excision has been established, the role of surgery in management of metastatic disease is less clear. The majority of patients with metastasis receive palliative treatment with radiation to achieve local control and chemotherapy for disseminated disease. However, if thorough evaluation reveals isolated or a limited number of metastases in a patient with a good prognosis, both cure and extended survival have been achieved with surgical “metastectomies”. Patients with extremity sarcomas who undergo pulmonary resections have 5-year survival rates up to 25%.¹² Similarly, hepatic lobectomy for colorectal metastasis is associated with 25–40% 5-year survivorship in selected patients.¹³

Finally, surgeons may be called upon to obtain tissue for diagnosis of a new mass. Depending on tumor size, either incisional or excisional biopsies are performed as a precursor to definitive resection or to establish a diagnosis for cancers treated nonsurgically. Incisional biopsies should always be oriented in a direction that facilitates future wide surgical excision.

Radiation

Ionizing radiation is defined as energy sufficient to release electron(s) from an atom or molecule. Most radiation agents use either photons or electrons to cause ionization. The quantity of ionization produced in air by a beam of radiation is termed the exposure and is measured in units of roentgens. The more clinically relevant measure is the absorbed dose, which is a calculation of the amount of energy absorbed per unit mass. This is quantified in joules per kilogram, or gray units (Gy). Upon entering tissues, the ionizing agent dose increases, but then degrades exponentially as its distance from the source increases in accordance with the inverse-square law.¹⁴

The mechanism whereby ionizing radiation achieves tumor cell kill is not completely understood. Ionizing radiation causes cellular damage directly through release of electrons

or indirectly by producing free radicals from water. Since oxygen increases the half-life of reactive radical species, radiation is most effective in oxygen-rich environments. When electrons or free radicals come into contact with biologically important molecules, such as DNA, detrimental effects occur. Although cells efficiently repair single-strand DNA breaks, double-strand breaks are less easily handled by cellular machinery. If sufficient DNA damage accumulates prior to the next mitotic cycle the cell is overwhelmed, leading to cell killing. When the interval between successive doses of radiation is increased, greater numbers of cells can repair DNA strand breaks. This principle is termed sublethal damage and provides the rationale for radiation delivery in fractionated daily doses ranging from 1.8 to 2.5 Gy. The success of radiation therapy is predicated on the fact that normal cells have a greater ability to repair sublethal damage between radiation fractions than tumor cells. Radiation therapy is most commonly delivered at a distance from the tumor called external-beam radiotherapy or teletherapy; however, it can also be administered as brachytherapy with high doses given directly into a specified area.¹⁴

Clinical use of radiation therapy began in the 1940s and 1950s after early pioneers in the field were able to minimize local complications such as radiation burns and secondary skin cancers. Although uncommon, radiation can be used as monotherapy for radiosensitive tumors such as Hodgkin's disease.¹⁵ For other tumor types equivalency between surgical excision and radiation therapy has been demonstrated. For example, treatment of T1/T2 prostate cancer with either radical prostatectomy or external-beam radiotherapy has comparable survivorship, but with different risk profiles for each therapy.^{16,17} Choice of treatment is based on patient preference and surgical risk factors as assessed by the treating urologist. Similarly, aerodigestive tumors of less than 2 cm respond equally well to either radiation or surgery. In the case of laryngeal neoplasms, radiotherapy is preferred due to its ability for preservation.¹⁸

Surgeons most commonly use radiation as part of neoadjuvant or adjuvant regimens in combination with extirpation for solid tumors. These two modalities complement each other to improve locoregional control. While surgery fails at tumor margins where cell counts are low or microscopic, radiation works best at the periphery where oxygenation levels are highest. Radiation is least effective in the avascular center of necrotic tumor masses where oxygen tension is poor.¹⁹

The efficacy of radiation therapy in reducing local recurrence has led to an increase in use of this modality for many cancer types. This increase is amplified by trends towards minimization of surgical extirpation and the use of neoadjuvant chemotherapy with resultant tumor down-staging. The increased role of radiation therapy in cancer management has led to refinements in its delivery. In the past, radiation was administered in the neoadjuvant setting with the goal of rendering microscopic tumor deposits, spilled inadvertently at the time of resection, incapable of cell division. However, technical difficulties and increased complication rates, such as wound breakdown and infection associated with this schedule of radiation, have led to its preferred use in the adjuvant setting for many cancers. Additionally radiation is a known independent risk factor for the development of postsurgical lymphedema as well as secondary skin malignancies.²⁰

Although the increased rates of wound-healing complications following surgery in irradiated tissues have been thought to be related to the harmful effects of radiation on the local blood supply, the exact cause(s) of this increased risk remains unknown.²¹ In fact, studies have suggested that radiation injury causes depletion of local tissue stem cells and that restitution of these cells with stem cell injections can improve tissue healing.²² Interestingly, recent studies have called into question the ability of radiation to improve survival, and as such suggest the need for more nuanced patient selection and risk stratification.²³

Concerns about toxicity and tissue injury after radiation have led to the development of a number of modalities aiming to increase the precision of radiation delivery. **Intensity-modulated radiation therapy (IMRT)** is an example of this approach combining 3D CT scans and computer software to optimize radiation simulation and delivery. During treatment, the intensity of the radiation beam is modulated by computerized X-ray accelerators enabling delivery of radiation to three dimensional tumor shapes thereby minimizing injury to the surrounding regions. For these reasons, IMRT has gained favor in the treatment of prostate, lung, head and neck, and brain lesions. In addition, recent studies have shown that IMRT can decrease cardiac and pulmonary toxicity in left-sided breast cancers. Recent studies have focused on demonstrating survival benefits to IMRT and decreasing long-term complication rates of radiation.²⁴⁻²⁶

Proton beam therapy is a type of radiation therapy in which a beam of protons (rather than electrons) is used to deliver radiation to the tumor bed. Because these particles are bigger than conventional radiation therapy, the delivery of the treatment dose can be more precisely controlled limiting surrounding tissue and exit dose delivery. These radiation delivery treatments are more complex than conventional therapy since a particle accelerator is required to generate the proton beam. The use of different particle sizes enables radiation oncologists to target tumors at different depths delivering the maximum peak of radiation (called Bragg Peak) at a precise point. The use of multiple photons generated from multiple particles (with variable penetration capacity) enables peak radiation delivery to the entire tumor bed.^{27,28}

Brachytherapy is radiation therapy that is delivered internally to the wound bed after tumor extirpation. In some cases, the radiation source can be placed without tumor extirpation or within the tumor itself to increase radiation dose delivery. This approach enables radiation oncologists to place the radiation source in very close approximation to the tumor bed thereby limiting radiation injury to surrounding tissues or external skin. In this manner, radiation therapy can be delivered safely in some cases even in patients who have been previously treated with external beam radiotherapy.^{29,30}

Chemotherapy

The goals of chemotherapy are similar to those of radiation, namely preferentially to kill cancer cells relative to normal tissues while minimizing toxicity. The success of chemotherapy is due to the fact that normal cells have improved ability to repair damaged DNA and survive relative to cancer cells. For chemotherapy to be successful, complete eradication of all tumor cells is essential. Agents that kill 99.99% of 10^9 tumor cells, the approximate number of cells in a 1-cm mass,

allow a tumor burden of 10^5 cells to remain. Since agents are unlikely to kill every tumor cell in a single administration, chemotherapies are delivered in several rounds to achieve maximal cell killing. Administration of chemotherapy in fractions takes advantage of the fact that some agents are effective only in certain stages of the cell cycle (termed kinetic resistance) and minimizes toxicity at each time point by allowing decreased dosing.³¹ Furthermore, combination chemotherapy using agents with different mechanisms of action and toxicities allows maximal tumor killing while minimizing host side effects. Recognition of chemotherapy toxicity has led to modifications such as regional administration, which allows for increased drug doses with reduced systemic side effects. Examples of this application include isolated limb perfusion for patients with melanoma in-transit metastases or hepatic artery infusion pumps for colorectal liver metastasis.^{32,33}

Chemotherapeutic agents such as nitrogen mustard and methotrexate were first introduced in the 1940s with the intention of avoiding surgery altogether. While effectiveness of chemotherapeutics as single-modality treatment for hematologic malignancies such as leukemia and lymphoma has been demonstrated, their efficacy in primary treatment of solid tumors has not been borne out in most cases. Exceptions include chemotherapy for subtypes of testicular cancer and combined chemoradiotherapy such as the Nigro protocol for anal cancer.^{34,35} A common indication for chemotherapy in the management of solid tumors is for palliation of patients with metastatic disease who are ineligible for curative surgery. In such cases, chemotherapy is administered with the intent of prolonging survival and improving quality of life.

Surgeons most frequently encounter chemotherapy as part of neoadjuvant or adjuvant treatment in combination with tumor excision. Examples of tumors commonly treated in this manner include breast, colon, and head and neck cancers. Synergy between surgery and chemotherapy is exemplified in the case of extremity sarcomas. Previously patients with osteosarcomas were treated with amputation; however, the introduction of neoadjuvant chemotherapy has increased rates of limb preservation with equivalent long-term survival.³⁶

Immunotherapy and biologics

Passive and active immunotherapies are newer forms of cancer treatment that use immune mechanisms to kill tumor cells. In passive immunotherapy the host immune system remains quiescent while therapeutic agents are introduced to eradicate tumor cells. The most common application of this treatment is delivery of monoclonal antibodies against specific tumor antigens (Fig. 11.2). Advantages of this approach are the highly specific nature of the therapy that theoretically decreases both side effects and toxicity. A widely used agent is trastuzumab, a monoclonal antibody that binds to the extracellular segment of the HER2/neu receptor, over-expressed in approximately 25% of breast cancers.^{37,38} Biologics such as trastuzumab and pertuzumab are commonly used as components of neoadjuvant regimens.³⁹

Adoptive immunotherapy is an alternative form of passive immunotherapy wherein cells with antitumor activity are introduced into the host (Fig. 11.3). An example would be *ex vivo* manipulation of host autologous tumor-infiltrating lymphocytes, which have a naturally occurring reactivity to

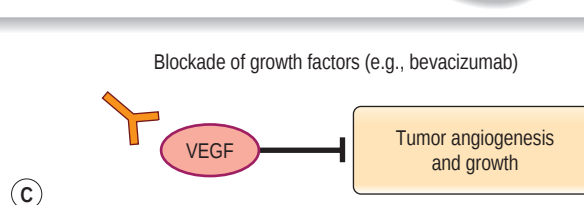

Fig. 11.2 Passive immunotherapy with monoclonal antibodies (mAb). **(A)** Monoclonal antibodies can act by binding a cell surface molecule that acts as a signal transducer. Antibody binding to this molecule inhibits its ability to transduce signals and activate downstream pathways that confer the malignant phenotypes of cell cycle dysregulation, cellular survival, and metastatic potential (e.g., trastuzumab). **(B)** Monoclonal antibodies can contribute to immunotherapy by cytotoxic effects (e.g., rituximab). Antibody binding to tumor-specific antigen can lead to complement fixation and activation, with ultimate formation of the membrane attack complex that punches pores in the tumor cell membrane. Antibody binding may also cause the activation of cytotoxic natural killer cells or phagocytic macrophages. **(C)** Finally, monoclonal antibodies can bind and block the activity of growth factors that are necessary for tumor maintenance. An example of this is bevacizumab, which binds vascular endothelial growth factor (VEGF) and therefore inhibits tumor angiogenesis.

Fig. 11.3 Adoptive transfer of autologous tumor-infiltrating lymphocytes. Lymphocytes are obtained and cultured from tumor specimen. Lymphocyte proliferation is stimulated with interleukin-2 (IL-2). Cells with specificity are isolated and expanded. Patient myeloablation is achieved with chemotherapy and radiation. The expanded antitumor lymphocytes are readministered, often along with IL-2.

cancer, in the presence of IL-2 to increase cytolytic potential or tumor antigen recognition.⁴⁰ Studies are currently evaluating the utility of this therapy for the treatment of melanoma.⁴¹

Active immunotherapy describes protocols in which the host immune system is directly stimulated by presentation of antigenic materials. If the antigenic material causes generalized stimulation of the immune system, it is considered nonspecific stimulation (Fig. 11.4). The best-known immunostimulant agent is bacillus Calmette-Guérin (BCG), an attenuated form of bovine tuberculosis bacillus. Although its mechanism of action is unclear, it has proven benefit in the treatment of superficial bladder cancers, with less promising results as a therapy for melanoma.⁴² Infusions with cytokines are another nonspecific form of active immunotherapy. For example, melanoma is a frequent target for agents such as interleukin-2 and interferon-alpha because it is the tumor with the most immunogenic response.^{43,44}

Agents that elicit a targeted response to either tumor antigens or effector cells are considered specific (Fig. 11.5). The best example of specific active immunotherapy is development of vaccines derived from antigens expressed on patients' cancer cells. The highly specific nature of this therapeutic approach underscores its limitations. For example, multiple patients' tumors may express different peptide antigens or alternatively different subclonal populations may exist within a single individual.

The latest generation of antineoplastic agents, called biologics, targets molecular pathways identified from basic science tumor biology. In contrast to traditional methods, which develop drugs through trial-and-error testing, drug creation in this manner is referred to as rational design since targets are specified *a priori*. Since many biologics are antibodies, they may be considered as forms of passive immunotherapy. The earliest example, imatinib (Gleevec), was designed to block the abnormal gene product of the Philadelphia chromosome,

Fig. 11.4 Active immunotherapy with a nonspecific agent such as bacillus Calmette-Guérin (BCG). Administration of the agent causes a nonspecific inflammatory reaction with attendant cytokine release. This results in activation of neutrophils, natural killer (NK) cells, and macrophages. These cells in turn release various cytokines, including interleukin-2 (IL-2), tumor necrosis factor-alpha (TNF-α), and interferon gamma (IFN-γ). These cytokines in turn lead to activation of lymphocytes and resultant tumor cell killing.

the constitutively active Bcr-Abl tyrosine kinase.⁴⁵ Clinical efficacy with imatinib has led to targeting of other oncogenes such as vascular endothelial growth factor with bevacizumab (Avastin) and CD20 with rituximab (Rituxan). As the newest class of antineoplastic agents, the role of biologics in the chemotherapeutic armamentarium is under investigation.

Fig. 11.5 Active immunotherapy with tumor vaccination. A variety of approaches to tumor vaccination have been applied, with variable results. An approach that has been advocated recently utilizes *ex vivo* activation of the antigen-presenting dendritic cell (DC). Immature DCs are expanded *ex vivo*. They are then exposed to a tumor-specific antigen and stimulated. The resultant mature DCs are administered to the patient. These cells act as antigen presenters, leading to activation of T cells with specific antitumor activity.

With widespread availability and use, plastic surgeons will increasingly operate on patients who receive them. Few data are available about surgery in this setting, but case reports suggest angiogenesis inhibitors such as bevacizumab contribute to wound breakdown since neovascularization is a key component of normal wound healing.⁴⁶

Photodynamic therapy

Photoradiation uses light within the visible spectrum to produce energy within cells. The most widely known application of photoradiation is lasers. Chemicals called photosensitizers, which are preferentially taken up by cancer cells relative to normal tissues, respond to light by producing free radicals. When light is shone on these cells, accumulation of energy leads to thermal damage and cell killing.⁴⁷

Since photodynamic therapy requires light to be activated, its utility is limited to superficial tumors. Photodynamic therapy is currently being used for the treatment of advanced esophageal and non-small cell lung tumors and is under investigation for oral, skin, and other cancers.^{48,49}

Pathobiology

Understanding of tumor cell biology provides a foundation for current clinical management of cancers.

Critical mass

Normal cells tend not to overcrowd one another and align themselves in an orderly fashion. In contrast, tumor cells lose this propensity and grow by overlapping each other. Tumor cells grow in a logarithmic fashion, quantified as the doubling time. Each tumor grows at a different rate so doubling times can vary between 2 and 200 days.^{50,51} Tumors are generally not detectable until they reach approximately 1 cm in diameter. Depending upon the doubling time, a tumor may be present in a patient for years before it becomes palpable. Understanding this concept affords the oncologic team sufficient time to evaluate newly diagnosed patients properly and thoroughly without rushing therapy. The first step, when technically feasible, is to obtain a biopsy of a tumor mass to establish the cell type and correct diagnosis. Excisional, incisional, or needle biopsies are performed depending on the size and location of the tumor. In some cases, for example, renal cell cancer, needle biopsy or incisional biopsies may be contraindicated as these procedures can cause peritoneal seeding. Tissue diagnosis is usually correlated with imaging studies such as computed tomography scans or magnetic resonance imaging to identify distant and regional tumor spread. Supplied with this information, informed decisions can be made with the patient about the best treatment and timing of adjunctive therapies relative to surgery.

Tumor margins

Variability in the distribution of tumor cells within a given tissue sample can hamper the identification of malignant cells in tissue sections. For example, if 10% of cells in a specimen have a malignant phenotype they are easily visualized using a microscope. However, if the number of malignant cells decreases to 0.1% or 1 in 1000, unless clustered together,

identification of these cells can be challenging and may require more sensitive measures such as immunohistochemistry (to label tumor antigens). Even these more sensitive measures may miss small foci of cancer metastases, therefore resulting in false negative diagnosis. Accurate diagnosis of surgical margins and biopsy specimens is critical since false negative findings can have a significant effect on diagnosis and treatment.

Clinical findings illustrate this concept. For example, patients with head and neck squamous cell cancers who undergo prophylactic lymphadenectomy have significant rates of local recurrences despite absence of tumor cells on final pathology.⁵² A second example can be seen in rectal cancers with negative margins on initial resection. Evaluation of patients with locally recurrent disease shows that 50% occur at the suture line despite negative histology.⁵³ Tumor recurrence in these scenarios may be attributable to microscopic tumor deposits not detected on pathologic evaluation.

Laboratory studies have also demonstrated the presence of microscopic tumor cells. Examples exist in both head and neck and melanoma specimens where cancer cells cannot be detected in routine histology, but have been successfully grown *in vitro*.^{54,55} More recently, molecular biology techniques such as polymerase chain reaction and immunohistochemistry have been used to perform molecular ultrastaging of histologically node-negative patients for identification of microscopically invisible tumor deposits. Whether such small tumor burdens are clinically significant is the subject of further investigation.⁵⁶

The aforementioned examples provide justification for multimodality treatment of solid tumors managed primarily with surgical extirpation. Although margins are frequently reported as “negative”, recurrences often occur. Chemotherapy or, more commonly, radiation is used in these settings to treat potentially viable occult tumor cells. Alternatively, it should be noted that the immune system has the potential to eradicate residual tumor cells remaining after extirpation. Review of patients with positive margins of basal cell cancer demonstrate recurrence rates of only 20–30%, suggesting the body’s capacity to destroy small numbers of cancerous cells.⁵⁷ Ideally the goal of cancer diagnosis is to identify patients accurately with microscopic spread of tumor to avoid unnecessary delivery of adjuvant agents that have untoward side effects and toxicities.

Classification

Tumor classification can be based on a number of different factors, including morphology, degree of differentiation, and histologic cell type. Classification schemes differ for each tumor type since factors that determine behavior are variable. Retrospective studies have identified tumor characteristics that may be used to predict the clinical behavior of the tumor type. For example, sarcoma behavior correlates with the number of mitoses identified per high-power field or histologic subtype.^{58–60} In contrast, prognosticators for breast cancer include tumor size, lymph node status, and hormone receptor expression.^{61–64} The principal goal of classification schemes is to substratify tumors to predict clinical behavior more accurately and guide therapy. Although recent advances have been made in this field, the quest for more accurate diagnosis and prognostication of tumor behavior is a major source of

current research. In the future, the goal is to identify tumors based on “genetic signatures” that enable not only more accurate diagnosis, but also targeted treatment.

The oldest classification system is based on clinical findings. Here, staging is based on degree of tumor spread, presence of lymph node involvement, and presence of distant metastasis by either radiography or biopsy. The widely used TNM system expounded on clinical classification systems in an attempt to stratify patients further into prognostic groups. In this system, tumor (T) represents the extent of the primary tumor as measured in size, depth of invasion, or degree of anatomic involvement. Node (N) enumerates involvement of lymph nodes, such as the number of affected nodes or node size. Metastasis (M) reflects the involvement of distant organs.

Other classification systems rely on tumor morphology as the basis for prognosis. For example, Lund’s classification for basal cell carcinomas is based upon descriptive features of the tumor such as nodular (well-defined margins), ulcerative, morphea and sclerosing patterns (indistinct margins). In this system, the presence of either morphea or sclerosing features is associated with a more aggressive and problematic course.⁶⁵ A second example is the morphologic classification established by Clark for melanoma, which includes lentigo maligna, superficial spreading, nodular, acral, and desmoplastic variants.⁶⁶

Histologic classification systems use histologic cell type or category to stratify clinical outcomes. Examples of histologic grading systems include salivary gland tumors, which are separated into mucoepidermoid, adenoid cystic, acinic cell, and squamous cell subtypes.⁶⁷ Clark’s histologic system categorized melanomas by level of invasion into the papillary and reticular dermis and subcutaneous fat.⁶⁶ Using this approach, determination of the depth of invasion was subjective with poor interrater reliability. Subsequently, Breslow’s system was developed which more objectively quantitated tumor thickness by measurement with a micrometer attached to the microscope field.⁶⁸

More recently, molecular biology concepts have been applied to tumor classification. Knowledge of the transcriptome and proteasome of tumors has led to identification of unique molecular signatures for each tumor that predict clinical behavior. An example is the reproducible and highly specific molecular signature of the clinically aggressive triple-negative (absent for ER/PR/HER2 receptors) breast tumors.⁶⁹ Through use of basic science techniques, investigators aim to subclassify tumors on a molecular level to refine staging schemes and provide tailored therapy.

Management

The oncologist’s goal is to apply available treatment options, both surgical and nonsurgical, to minimize morbidity while enabling patient cure. In addition, the relative value of reconstruction in restoration of organ function and cosmesis is not equivalent in all scenarios and may play a role in choosing an oncologic regimen. For example, laryngeal cancer treatment with radiotherapy is strongly preferred over laryngectomy since current methods of voice reconstruction are inadequate.

In contrast, many breast cancers are treated equally well with either lumpectomy and radiotherapy or mastectomy alone. These situations require detailed consultation with a

comprehensive oncologic team about the risks and benefits of each therapy with informed decision-making by the patient. Furthermore, the availability of highly effective autologous and implant-based breast reconstruction techniques may further influence the decision to proceed with simple mastectomy. Similarly, limb preservation for osteosarcomas has only become possible through use of neoadjuvant chemotherapy and functional reconstructions with allografts or endoprostheses. These examples highlight a paradigm shift in ablative strategies over the last century from a “Halstead approach” to modern treatment that relies on advances in both multimodality therapy and reconstruction to manage solid tumors.

Beyond primary tumor mass excision, the treatment of draining lymph nodes is an important part of solid tumor management. Since carcinomas drain through regional nodal basins, in contrast to sarcomas that spread hematogenously, removal of regional lymph nodes is crucial for these malignancies. Regional lymphadenectomy is routinely performed as part of staging to determine prognosis and for its potential therapeutic value.^{70–74}

For patients with clinically palpable nodes at the time of tumor resection, removal of involved nodes is generally performed to achieve regional control by preventing mass effect and skin breakdown. In cases with no clinical evidence of lymph node involvement either on examination or radiographically, the timing of lymphadenectomy is controversial. Lymph node dissection can be performed either at the time of initial tumor extirpation, termed prophylactic or elective lymph node dissection (ELND), or when the tumor subsequently recurs in a nodal basin (therapeutic lymph node dissection, or TLND). ELND is not routinely recommended for two reasons. First, regional lymphadenectomy leads to increased morbidity such as extremity lymphedema or complications of surgical dissection such as nerve damage. Second, ELND has not clearly demonstrated improved survival compared to TLND for malignancies such as melanoma.⁷⁵ Ideally, ELND should be restricted to cases with high probability of occult regional tumor spread such as head and neck cancers with a large primary tumor.⁷⁶

The introduction of the sentinel lymph node concept by Morton *et al.* has further altered surgical management of clinically negative regional lymph node basins.⁷⁷ The sentinel node concept is based on the fact that tissues drain into regional nodes in a reproducible and orderly fashion. After injection of either radioactive colloid or blue dye into the tumor, the first or sentinel node draining the basin is excised to be examined for tumor involvement. The status of the sentinel node is representative of the entire regional nodal chain, suggesting whether or not ELND should be performed. Through careful intraoperative identification of the sentinel node and thorough histologic analysis, false negative rates for sentinel node biopsy now range from 0 to 11%.^{78,79} A subset of patients with negative sentinel nodes on hematoxylin and eosin stain will have micrometastatic disease present on immunohistochemistry. The consequence of such small tumor deposits is unclear since these patients have similar survivorship to controls.⁸⁰ An additional benefit of sentinel node mapping is that, since only a single node is harvested, more thorough histologic and pathologic evaluation is performed of the specimen for improved nodal staging accuracy.

Theoretically, sentinel node mapping should decrease the number of unnecessary regional lymphadenectomies performed with associated morbidity. Rates of extremity lymphedema with sentinel node mapping have decreased to 5% compared with 35% for complete lymphadenectomies.^{81,82} Currently sentinel node mapping is performed for breast cancer and melanoma while reliability of the concept in head and neck, lung, and uterine cancers is under investigation.⁸³⁻⁸⁵

A second major issue to consider when performing lymphadenectomy is the extent of dissection. Arguments supporting extended or radical lymphadenectomy are that greater node removal more accurately stages disease and failure to remove these nodes leaves residual cancer cells behind. For example, colon cancer guidelines recommend that at least 12 nodes be evaluated histologically to avoid a false-negative nodal status.⁸⁶ Arguments against routine use of extended lymphadenectomy include increased morbidity of dissection and lack of a survival benefit compared to limited dissections in randomized trials.

A comprehensive discussion of cancer surveillance is beyond the scope of this chapter, though some points are worth mentioning. Although the premise behind surveillance is to improve outcome through early detection, few protocols demonstrate an actual survival benefit. For example, head and neck patients with asymptomatic recurrences identified through screening methods demonstrate no survival difference compared to patients who presented with symptoms.⁸⁷

Concerns have also been raised that reconstruction may obscure recurrence detection, but data do not support this contention. Maxillectomy defects reconstructed with flaps, as opposed to obturators, demonstrate statistically comparable times to recurrence.⁸⁸ Similarly, for breast cancer neither implant nor autologous reconstruction has been associated with a delay in diagnosis of recurrent disease.^{89,90} Recurrences after transverse rectus abdominis myocutaneous flap reconstruction can be successfully managed with local excision and flap salvage in 80% of cases. Regardless of the type of breast reconstruction performed, recurrent disease is detectable on physical exam, not mammography.

Conclusion

Today, the most common treatment for solid tumors remains surgical excision; however, the last century has demonstrated the advantages of multimodality therapy using chemoradiation. Refined staging and increased knowledge of pathobiology have allowed individualized tumor management with development of targeted treatment regimens. It is incumbent upon plastic surgeons to understand the principles of cancer management in order to perform reconstructions that minimize postsurgical complications, thereby allowing patients to receive adjunctive therapy in a timely manner.

Stem cells and regenerative medicine

Michael S. Hu, Ruth Tevlin, Derrick C. Wan, H. Peter Lorenz, Geoffrey C. Gurtner, and Michael T. Longaker

SYNOPSIS

- There exists a significant clinical need for tissue reconstruction and regeneration.
- Stem cells are a key building block to any tissue regeneration or engineering strategy.
- Stem cells can be derived from multiple sources and tissues at various stages of differentiation.
- Stem cells can have different *in vitro* and *in vivo* capabilities and are at different stages in bench and bedside research:
 - embryonic stem cells
 - postnatal and somatic stem cells
 - adipose-derived stromal cells (ASCs)
 - mesenchymal stem cells (MSCs)
 - tissue-specific stem cells
 - induced pluripotent stem (iPS) cells
- Prospective clinical applications for stem cell therapy will likely require multidisciplinary approaches employing tissue engineering and inductive therapies (including biomimetic matrices, gene therapy, small molecules, and growth factors).

- Mesenchymal stem cell differentiation has been elucidated using specific *in vitro* and *in vivo* protocols.
- Adult, or tissue-specific, stem cells are undifferentiated cells that are found in almost all tissues and organs after embryonic development.
- Postnatal stem cells can be reprogrammed into an “embryonic-like” state called induced pluripotent cells.

Discussion of biomedical burden (Fig. 12.1)

As the global population ages and expands, the associated incidence of pathology secondary to congenital, postsurgical, post-traumatic, vascular, and degenerative etiologies (such as arthritis, osteoporosis, chronic wounds, post-oncologic resection) also continues to increase. In 2007 it was estimated that the United States alone spent over 26 billion dollars on treatment for diseases of the musculoskeletal system, with an average annual growth of 8.5% (second highest growth of all body systems).¹ The American Society of Plastic Surgery additionally estimates that almost 5.8 million reconstructive procedures were performed by plastic surgeons in 2014, with over 4.4 million cases performed for tumor removal and cancer reconstruction, and over 102,000 for breast reconstruction.²

Tissue reconstruction remains a significant challenge for plastic surgeons when treating patients suffering from traumatic injury, oncologic extirpations, and congenital anomalies. While synthetic prostheses, plates, and implants to correct soft-tissue defects have greatly improved the lives of millions of patients, such artificial tissues are plagued by suboptimal durability and increased risk of infection. While some of these problems have been mitigated by the use of cadaveric and autogenous grafts, the grafts too are limited by durability, availability, and donor site defects.

Plastic surgeons must thus struggle with the inadequacy of current implants and grafts, and the failure of these therapies to recapitulate the ability of dynamic living tissue to remodel and regenerate in response to environmental cues. To address this, the focus of reconstructive strategies must ultimately shift from simple tissue repair to tissue regeneration. Tissue

Introduction

- Three characteristics that define a stem cell are:
 1. Self-renewal: stem cells can expand and give rise to a clonal population of cells through cell division.
 2. Clonality: stem cells are able to give rise to new stem cells.
 3. Differentiation potential: stem cells can differentiate *in vitro* and *in vivo* into multiple mature cell types and reconstitute a specific tissue type following transplantation.
- Stem cells can come from embryonic or postnatal sources.
- Embryonic stem cells exist in a more primitive pluripotent state than postnatal, somatic, and tissue-specific stem cells.

Fig. 12.1 Biomedical burden. Different tissue reconstructive challenges faced by plastic surgeons. From left to right, possible applications of tissue engineering include treatment of chronic wounds, post-cancer ablation, breast reconstruction, craniofacial reconstruction, and traumatic injury.

regeneration, in short, involves the use of a biologically active scaffold, seeded with a pluripotent, self-renewing cell type such as stem cells (Fig. 12.2). The synergy of the biomimetic scaffold with a competent cellular element (e.g. stem cells) will ideally allow the regeneration of tissues in response to injury.

Stem cells are defined functionally as a clonogenic population of cells capable of self-renewal and differentiation into committed progenitors. These progenitors can then differentiate further into mature cell types and form functional tissues.³ Traditionally, stem cells have been divided into two categories based on their differentiation potential: pluripotent stem cells and multipotent stem cells. Pluripotent stem cells (also known as embryonic stem cells) are capable of differentiating into any cell type in the body, whereas multipotent stem cells (also called adult stem cells) are more restricted in their potential and can give rise to multiple, but not all, cell lineages. Recently, in addition to this traditional stem cell classification, a new class of stem cells has been described, called induced pluripotent stem cells (iPS cells). iPS cells are derived from genetically reprogrammed adult cells and are believed to have the same differentiation potential as embryonic stem cells.

Why stem cells and regenerative medicine should be of interest to plastic surgeons

Plastic surgeons are optimally positioned to utilize adult stem cell populations in clinic as they have direct access to a plentiful supply of adult stem cells. Specifically, plastic surgeons can obtain large quantities of adipose tissue from liposuction and body-contouring procedures. From this tissue, adipose-derived stromal cells may be extracted for therapeutic use.

Fig. 12.2 Differentiation of pluripotent stem cells down different multipotent lineages. An embryonic stem cell is a pluripotent stem cell, whereas an adipose-derived mesenchymal cell is a mesodermal multipotent stem cell.

Ideally, fully developed stem cell technology would enable the utilization of prefabricated biomimetic scaffolds seeded with these cells to address a wide range of soft tissue, skeletal, muscle, cartilage, vascular, or joint defects. Recent studies have shown that there may be differences in the osteogenic and adipogenic potential of adipose-derived stromal cells based on the subcutaneous region from which the cells are harvested. Therefore, surgeons in the future may tailor the region from which they harvest the therapeutic cells to patient-specific needs.⁴

In addition, the potential for clinical utilization of human stem and stromal cells is widely acknowledged and has prompted some individuals to store their own tissues for possible future use. One example of this is the banking of umbilical cord-derived blood.⁵ Similarly, various other adult stem cell types can be frozen for long-term storage.

Human embryonic stem cells

Definitions

Research in hESCs is a rapidly developing field and has attracted increasing attention over the last fifteen years. The ability of hESCs to produce any cell type found in the human body has yielded many encouraging new avenues of investigation. Furthermore, hESC research promises to provide a deeper understanding of cellular biology while generating new treatment modalities for many diseases.^{37,38} In addition, the ability of stem cells to repair and regenerate tissue hints at the possible restoration of organ damage once thought to be permanent and return of function once considered irreversibly lost. Despite recent controversy surrounding political and ethical concerns over the research and clinical use of these cells, hESCs continue to be a promising cell source in the field of regenerative medicine.

The term “embryonic stem cell” was coined by Gail Martin to distinguish them from previously described pluripotent embryonal carcinoma (EC) cells derived from teratocarcinomas.²⁹ ESCs possess three essential characteristics: (1) derivation from a pre-implantation or peri-implantation embryo; (2) the capacity to self-renew and proliferate in a prolonged undifferentiated state; and (3) the ability to form derivatives of all three embryonic germ layers.³⁹

As an extension of early work on ESCs in mice, hESCs were first isolated in 1998.³⁹ Donated fresh cleavage-stage human

Historical perspective

Current understanding of clonal stem cell populations has only been validated within the last 40 years. Prior to the 1960s all dividing cells were thought to contribute to tissue growth and turnover, and were generally classified as resident stem cells.³ However, a revolutionizing publication in 1961 redefined existing perceptions of stem cells by isolating a specific population of self-renewing cells in the bone marrow.⁶ This particular stem cell population was discovered by infusing a lethally irradiated mouse with bone marrow cells capable of migrating to the spleen and giving rise to hematopoietic cell nodules. The cells from the nodules were then proven to have been derived from a single cell. Cells capable of giving rise to clonal populations were named “colony-forming units” and eventually shown to be short-term hematopoietic cells. Studies such as this provided the framework for our current understanding of the undifferentiated self-renewing cell population.

The presence of mesenchymal stem cells, a type of adult stem cell, in the bone marrow was first suggested in the late 19th century by Cohnheim, who proposed that fibroblasts involved in peripheral wound healing were derived from the marrow compartment.⁷ In the 1970s, Friedenstein *et al.* demonstrated the existence of “fibroblastoid” cells within guinea pig bone marrow by flushing out cells onto plastic culture dishes and discarding the non-adherent cells.⁸ The remaining spindle-like cells were heterogeneous in appearance but appeared to be capable of forming colonies *in vitro*, giving rise to the term colony-forming unit fibroblasts.^{8,9} When these cells were subsequently transplanted into subcutaneous pockets, they successfully formed heterotopic bone tissue.⁸ Using similar methods, Castro-Malaspina *et al.* effectively isolated colony-forming unit fibroblasts from human bone marrow.¹⁰ Since these early studies, subsequent investigations have shown that these cells could be cultured *in vitro* and differentiated into several cell types within the mesenchymal lineage.^{11,12} What Friedenstein isolated would later be aptly renamed by Caplan to “mesenchymal stem cells.”¹¹

The fundamental characterization of MSCs as a truly multipotent population of cells is attributed to work by Pittenger and colleagues in 1999.¹³ Prior to this report, scientists were unsure whether bone marrow MSCs represented a heterogeneous mixture of committed progenitor cells, each with restricted potential, or individual cells capable of differentiating into fat, cartilage, bone, and muscle. Running human bone marrow aspirates from the iliac crest of over 350 donors through a density gradient isolation procedure resulted in a phenotypically homogeneous population of adherent cells. Flow cytometry analysis confirmed that over 98% of these adherent cells shared the same surface marker profile. Single cells were isolated from this population and re-expanded. These new descendant cells were shown to retain the ability to differentiate into adipocytes, chondrocytes, and osteoblasts.¹³ MSCs thus proven to have the ability to proliferate extensively while maintaining their multipotent nature were identified as true stem cells.

Historically, adipose tissues were presumed to function solely as a metabolic reserve responsible for processing, storing, and liberating high-energy materials in the form of cholesterol and triglycerides. However, scientists in the early 1960s described a stromovascular fraction (SVF) within adipose

tissue that contained fibroblastic-like cells.¹⁴ Subsequent research into this SVF cell type led scientists to believe that they represented an adipose progenitor cell with differentiation potential limited to adipose tissue.¹⁵ But in 2001, Zuk *et al.* demonstrated the ability of these SVF cells to undergo not only adipogenic but also chondrogenic, myogenic, and osteogenic differentiation.¹⁶ The cells were eventually renamed adipose-derived stromal cells or ASCs. Similar to MSCs, ASCs have since been shown to be capable of differentiating into cardiac cells and even neural progenitor cells *in vitro*.^{16–18} Additional investigation has revealed the differentiation potential of ASCs to be much greater than what was initially thought possible.^{18–24}

Cell surface markers on ASCs are similar to those of MSCs; both express CD105, STRO-1, CD29, CD144, and CD166.^{24,25} Due to the abundance and ease of isolation of ASCs in comparison to other adult stem cell populations, investigators have increasingly focused on the potential applications for ASCs in regenerative medicine. For example, numerous studies have demonstrated the regenerative potential of ASCs when seeded onto a polyglycolic scaffold to create an osteoid-like material.^{26–28}

Establishment of embryonic stem cells was first reported in 1981 using pre-implantation mouse embryos.²⁹ Cells from blastocysts were explanted into tissue culture and developed into four individual cell lines. When these cell lines were transplanted into syngeneic murine hosts, they formed well-differentiated teratocarcinomas, suggestive of pluripotent capacity.³⁰ However, early research using human embryonic stem cells (hESCs) was complicated by contentious political and ethical debate surrounding use of human embryos. Until recently, the creation of hESCs necessitated destruction of a human embryo, which inevitably raised various value-of-life objections. Many of these embryos, however, had already been destined for destruction as they were created for the purpose of *in vitro* fertilization, but had been stored long past their viable shelf-life.³¹

In 2009, President Obama expanded federal research funding beyond what had been previously authorized to include more than 100 existing cell lines, in addition to newly created hESCs sponsored by private or state-level funding.³² Under this new provision, federal funds cannot be awarded towards the creation of new stem cell lines if the creation involves the destruction of an embryo. In response to this restriction, scientists developed a novel method of hESC derivation that does not necessitate damage to the embryo.³³ Using a single cell biopsy technique similar to that used for pre-implantation genetic diagnosis, researchers were able to generate two new pluripotent cell lines without damaging the original embryo.³³ This approach additionally allows for potential generation of matched tissue for children born through *in vitro* fertilization.

An important concept in adult stem cell function is that of the stem cell niche, first proposed by Schofield in 1978.³⁴ A stem cell niche describes the microenvironment in which adult stem cells reside and includes signaling pathways and intracellular communications that permit adult stem cells to maintain their function as regenerative cells.³⁵ This structural unit is modulated by surrounding stimuli to sustain adult stem cell populations while also ensuring that they are appropriately activated. Studies in hair follicle, intestinal lining, and bone marrow have provided significant insight into the precise spatiotemporal regulation of this niche.³⁶

embryos produced by *in vitro* fertilization were obtained by Thomson *et al.* and cultured to the blastocyst stage, typically 4–5 days post-fertilization. From the inner cell mass (which ultimately forms the embryo), five separate hESC lines were established and successfully maintained in culture for 6 months in an undifferentiated state. All five lines retained the capacity to form teratomas after injection into immunodeficient mice. Histological examination of these teratomas revealed gut epithelium, cartilage, bone, smooth muscle, neural epithelium, ganglia, and stratified squamous epithelium. Similar findings were also described by Reubinoff and colleagues, who derived two additional hESC cell lines and demonstrated expression of the transcription factor Oct-4 in these cells. Oct-4 had previously been shown to be essential for the maintenance of pluripotential capacity in mouse ESCs.^{40,41}

The development of hESCs galvanized research into human embryogenesis, development of birth defects, and cellular mechanisms of a variety of pathologic states. In theory, hESC can be used to treat a wide variety of genetic diseases, cancers, diabetes, neurologic degenerative conditions, and spinal cord injuries. Actual translation into clinical use, however, has been hampered by problems with graft-versus-host disease. One potential solution to this involves the development of several hESC cell lines from variegated genetic backgrounds for tailored use in patients to minimize risk of rejection. Other strategies that have been proposed include the use of autologous donor adult stem cells or the more recently discovered iPS cell.^{13,17,42}

Concerns regarding xenogeneic contamination of stem cells during culture have also been raised. hESCs are traditionally cultured *in vitro* using mouse embryonic fibroblast (MEF) feeder layers.³⁹ Without MEF feeder layers, hESCs undergo rapid differentiation and lose pluripotency. A feeder-free culture system has been presented by Xu and colleagues employing Matrigel in medium conditioned by MEFs. However, even with this system, hESCs are still exposed to murine products in order to maintain pluripotency.⁴³ Fears of xenogeneic contamination were further substantiated in 2005, when Martin *et al.* reported the presence of a nonhuman sialic acid Neu5Gc on the cell surface of hESCs.⁴⁴ As humans are unable to generate this particular sialic acid, this finding likely represented uptake from media containing animal products and incorporation through glycosylation. When these hESCs and their derived embryoid bodies were exposed to human serum, rapid binding of immunoglobulin and deposition of complement occurred, ultimately resulting in cellular death.

Circumventing this problem necessitated the creation of a new stem cell line under murine-free conditions. To accomplish this, novel extracellular matrix-coated plates were developed from MEFs and sterilized prior to use.⁴⁵ When hESCs were cultured using these plates, undifferentiated proliferation was observed for 6 months and cells maintained the capacity to form all three embryonic germ layers. This system thus eliminated exposure of hESCs to potential contamination from serum and/or live feeder cells and minimized the risk of disease transmission through contact of cells with animal or human pathogenic agents.

Current concepts and research

Studies utilizing hESCs continue to dramatically revamp our contemporary understanding and treatment of disease

(Fig. 12.3). For instance, technologies developed from stem cell research can be used to manage spinal cord injuries, degenerative neurologic conditions, as well as a variety of genetic diseases. While stem cell investigators have also made significant strides in the fields of diabetes, cardiac, and hematopoietic/vascular research, treatment of spinal cord trauma and Parkinson's disease has recently received more high-profile attention.

The ability for ESCs to undergo neuronal differentiation was first demonstrated by Bain and colleagues in 1995.⁴⁶ After exposing mouse ESCs to retinoic acid, multiple cellular phenotypes were observed, a large percentage of which produced neuron-like outgrowths. Gene expression analysis of these cells revealed several neural-associated transcripts including neurofilaments, glutamate receptor subunits, and nerve-specific transcription factors. Furthermore, physiologic studies demonstrated that these neuron-like cells could generate action potentials. Paralleling these experiments, Schuldiner *et al.* induced neuronal differentiation from hESCs using both retinoic acid and nerve growth factor (NGF).⁴⁷ These neural progenitors were found to be capable of differentiation *in vitro* into astrocytes, oligodendrocytes, and mature neurons.^{40,48} When transplanted into the ventricles of newborn mouse brains, the hESC-derived neuronal cells distributed widely throughout the brain and integrated in a region-specific manner. These findings illustrated the ability of hESCs to respond to local environmental cues *in vivo* to differentiate into appropriate neural lineages. While only preliminary, the results underscore the potential of hESCs to provide novel therapies for the treatment of currently intractable neurological diseases.

Fig. 12.3 Use of embryonic stem cells. Embryonic stem cells can be used to study genetic changes, screen drugs and design novel therapies. EPC, endothelial precursor cell; ESC, embryonic stem cell; HSC, hematopoietic stem cell; MSC, mesenchymal stem cell.

hESCs have likewise shown promise in the field of diabetes research. At present, the only therapy that is potentially curative for type 1 diabetes is pancreatic islet cell replacement.⁴⁹ Unfortunately, donor shortage has severely limited this modality from becoming a widespread therapeutic solution. Furthermore, the risk of potential disease transmission and cellular rejection also place severe limitations on this treatment modality. The generation of glucose-sensitive insulin-secreting cells from mouse ESCs, however, has introduced a new potential source of cells for treatment of type 1 diabetes.⁴⁹ Culturing hESCs in suspension and allowing for embryoid body formation led to the detection of insulin-producing cells after 14 days of differentiation.⁵⁰ Immunohistochemical staining suggests that 1–3% of the cells are positive for insulin. More recent studies have cast some doubt on these numbers however, estimating their true incidence to be less than 1 per 100 000 cells.⁵¹ While further research is necessary, these studies nonetheless demonstrate the potential to derive cells capable of β -islet function and insulin release that could theoretically be used to replace lost pancreatic cells in patients with type 1 diabetes.

The study of cardiac tissue development has long been handicapped by the lack of a suitable *in vitro* model. The advent of hESC research, however, has also offered a potential avenue for progress to be made in this area. Kehat and colleagues first noted the presence of spontaneously contracting areas within hESCs cultured in suspension and plated to form embryoid bodies.⁵² Cells from these regions, which made up approximately 8% of the entire area, stained positively for a variety of cardiac markers, including myosin, desmin, troponin I, and atrial natriuretic factor. In addition, both positive and negative chronotropic effects were observed in the contracting cells following application of isoproterenol and carbamylcholine. Differentiation of hESCs into these cells was found to be enhanced by the application of 5-aza-2'-deoxycytidine and purified through density centrifugation to obtain a population of cells comprised of 70% cardiomyocyte progenitors.⁵³ In 2003, Mummery *et al.* provided the first demonstration of hESC cardiomyocyte differentiation through co-culture techniques with visceral endoderm-like cells.⁵⁴ This approach mitigated the need for spontaneous cardiogenesis and efficiently produced solid aggregates of beating cells consisting of 10–200 cardiomyocytes. Interestingly, these colonies could be frozen and were observed to resume beating upon thawing. Collectively, the findings strongly argue for the continued development of hESCs as a model for cardiac research. hESC ability to differentiate into cardiomyocytes *in vitro* and the development of technology to enrich these cells represent important initial steps towards the future clinical utilization of hESCs in heart disease.

Investigators have also developed procedures to induce the formation of vascular endothelial cells from hESCs. Endothelial cells play a critical role in repair and regeneration, and investigation into potential use of hESC-derived vascular cells in the treatment of vascular disease is highly clinically relevant.⁵⁵ Zambidis *et al.* first described the presence of mesodermal-hematoendothelial cluster colonies within embryoid bodies at days 6–9.⁵⁶ These colonies were found to consist of non-adherent cells expressing CD45, and gave rise to hematopoietic lineages, as well as adherent cells that expressed markers characteristic for vascular endothelium.

The hESC-derived endothelial cells were then isolated using fluorescence-activated cell sorting (FACS) for CD31 positive cells.⁵⁷ After expansion in culture, the cells were injected into immunocompromised mice and found to form microvascular networks. While their long-term stability is unknown, these derived endothelial cells represent the first step towards potential treatment of vascular disease and stimulation of ischemic tissue growth using hESCs. They also provide a foundation for future study of biomolecular mechanisms involved in blood vessel formation.

Clinical correlates

Clinical use of hESCs remains in its early infancy. The obstacles that must be overcome prior to wide clinical utilization include: risk of tumorigenicity, immunocompatibility, and successful isolation of a pure population of desired cell types for therapeutic use. Nonetheless, work continues on one of the most promising applications of hESCs: neuroregeneration. Preliminary work performed in the murine model has shown potential, leading to the first Food and Drug Administration (FDA)-approved clinical trial incorporating hESCs.

The capacity for regeneration of the central nervous system is limited, making the possibility of repair and return of function through utilization of hESCs particularly compelling. Following trauma, injuries to the brain and spinal cord can result in demyelination secondary to death of local oligodendrocytes.⁵⁸ While axons may be spared, action potential propagation nonetheless can become disrupted, resulting in irreversible loss of motor function. hESCs that have been differentiated into oligodendrocytes, however, can potentially be used to replace lost oligodendrocytes. As a proof of this concept, Keirstead and colleagues evaluated the ability for hESCs to incorporate, re-myelinate, and restore locomotion after spinal cord injury in rats.⁵⁹ In this study, spinal cord contusion injuries were induced in Sprague-Dawley rats at the T10 level using a controlled, reproducible force generator capable of delivering a sudden desired impact. Oligodendrocytes derived from hESCs were purified and delivered both above and below the place of contusion 7 days following injury through direct injection into the spinal cord. Histological analysis 8 weeks later revealed significantly greater density of re-myelinated axons when compared to control animals. More importantly, however, animals that received hESC-derived oligodendrocytes demonstrated significantly higher locomotor function scores, which continued to improve up to 1 month after the initial injury. These findings suggest that transplantation of hESC-derived oligodendrocytes may be an effective means of treating acute spinal cord injuries. Of note, no teratomas were observed in this study, suggesting pre-differentiation of hESCs prior to clinical use may obviate concerns surrounding risk of tumorigenesis.⁶⁰

The oligodendrocyte progenitor cell (OPC), a neural progenitor derived from human embryonic stem cells, has been identified as another promising cell population that could be utilized for clinical CNS regeneration. OPCs have the potential to commit to an oligodendroglial lineage and have been found in a number of animal studies to reduce loss of function following spinal cord injuries.^{61, 62} In 2015, Asterias Biotherapeutics announced the initiation of patient recruitment for a phase I/IIa clinical trial to test the safety and efficacy of OPCs in

individuals with complete cervical spinal cord injury (SCI). The trial is a continuation of the California Institute for Regenerative Medicine (CIRM)-funded clinical trial begun by biotechnology firm Geron in 2010 using the same kind of stem cell to treat thoracic SCI. None of the five patients from the initial Geron trial developed adverse effects such as tumors or inflammation from the therapy, and MRI scans performed throughout the follow-up period found decrease in the size of injury site and suggested that OPCs may have had some positive effect in preventing further spinal deterioration in four out of five patients. Despite these findings, the Geron trial was discontinued due to a reported change in business strategy within the company.⁶³ While it remains to be seen whether positive findings from rat studies can be clinically replicated, this represents an important first step towards the implementation of translational therapies using stem cells to treat human disease. Though full restoration of function following complete paralysis is not expected at this present time, there is hope that patients with less severe injuries may one day benefit from use of hESCs.⁶⁴

Postnatal and somatic stem cells

Adipose-derived stromal cells

Definitions and harvest

Adipose tissue contains a stromal population composed of three main types of cells: microvascular endothelial cells, smooth muscle cells, and multipotent cells. ASCs have the capacity to differentiate into adipocytes, osteoblasts, and chondroblasts *in vitro*.^{16,17,19,65,66} However, the origin of hASCs has not been clearly defined. Several laboratories have hypothesized that these cells represent pericytes surrounding blood vessels, which may explain their ability to differentiate into endothelial cells; others suspect they are a subpopulation of fibroblasts that reside within adipose tissue (Fig. 12.4).

ASCs, like stem cells from the bone marrow, have extensive proliferative potential and can self-renew, as well as undergo osteogenic, chondrogenic, myogenic, and adipogenic differentiation. This population can also be defined by its cell surface markers. ASCs have been shown to be positive for the following cell surface markers: CD105, STRO-1, CD29, CD144, and CD166. They have been shown to be negative for the following cell surface markers: CD3, CD4, CD11c, CD14, CD15, CD16, CD19, CD31, CD33, CD38, CD56, CD62p, CD104, and CD144.^{24,25}

ASC harvest

Human ASC harvest can be performed on human lipoaspirate or resected adipose tissue (Fig. 12.5). Lipoaspiration removes the necessity for mincing adipose tissue, and ASCs have been shown to retain differentiation potential even following ultrasonic-assisted liposuction.⁶⁷ If fat has been harvested from multiple anatomic locations, these specimens should be labeled accordingly and kept separate as material differences exist in the differentiation capacity of adipose cells mined from different subcutaneous depots (Fig. 12.6).⁴

Fig. 12.4 Unknown origin of human adipose-derived stromal cell (hASC). Adipose-derived stromal cells are thought to be derived from adipocytes or fibroblasts or from perivascular mural cells known as pericytes.

Following harvest, the adipose tissue should be processed in a sterile cell culture environment as soon as possible (Fig. 12.7). Adipose specimens should first be washed in dilute Betadine, followed by two phosphate-buffered saline (PBS) washes of equal volume. The tissue should then be digested with an equal volume of 0.075% (w/v) type II collagenase in Hank's balanced salt solution at 37°C in a water bath with agitation at 140 rpm for 60 minutes. Every 15 minutes during digestion, the fat should be agitated and vented. Next, the collagenase digest should be inactivated by adding an equal volume of PBS with 10% fetal bovine serum (FBS) and 1%

Fig. 12.5 Human liposuction of thigh.

Fig. 12.6 Different locations from which liposuction fat can be harvested. These locations have been shown to demonstrate different osteogenic and adipogenic potentials.

penicillin/streptomycin. The stromal vascular fraction is then pelleted via centrifugation at 1000 rpm for 6 minutes. The supernatant is discarded and the cell pellet resuspended and filtered through a 100- μ m cell strainer to remove undigested tissue fragments. The cells are pelleted and resuspended in growth media, and primary culture is established in tissue culture plates incubated at 37°C in an atmosphere of 5% CO₂. Cell counting can be challenging given the large number of erythrocytes in the final cell pellet. However, we do not recommend a red cell lysis step as we believe this decreases the viability of the ASCs. On average, 10 mL of starting adipose tissue will allow the harvest of 1 million hASCs.

Mouse ASC (mASC) harvests are done in a similar manner. The first step involves harvesting the inguinal fat pad bilaterally from at least four mice. Here, it is imperative to mince the adipose tissue finely prior to the digestion step. Subsequently, the steps are the same as described above for hASCs: a

digestion step, followed by neutralization, centrifugation, filtration, and plating.

Current concepts and research

Difference between mouse and human ASCs

The study of mASCs is attractive due to the relative ease of cell harvest and the availability of laboratory mice. However, important differences exist between mouse and human ASCs. For example, hASCs have been observed to have a significantly more robust *in vitro* osteogenic capacity when compared to mASCs.^{68,69} In order to undergo significant *in vitro* osteogenesis, mASCs require an additional osteogenic stimulus such as retinoic acid.⁷⁰ Moreover, cytokines such as fibroblast growth factor (FGF)-2 abolish osteogenic differentiation in mASCs, whereas hASC osteogenic differentiation proceeds relatively uninhibited both in the presence and absence of FGF-2.^{69,71}

In our laboratory, we observed that ASCs, whether derived from mouse or human origin, contribute to osseous healing of mouse cranial defects.^{72,73} For example, a critical-sized mouse calvarial defect shows no healing without ASC engraftment even up to 16 weeks post-injury. Upon hASC engraftment, however, significant bony healing is observed in as little as 4 weeks post-injury.⁷³

Enrichment based on cell surface receptors

While substantial progress has been made in the study of ASCs, further progress is hampered by the heterogeneity of the cell population. We believe that a select subpopulation of cells with robust ability to differentiate along an osteogenic lineage can be further purified from the current ASC population (Fig. 12.8). Selecting for this enriched subpopulation of ASCs can help maximize outcomes of cell-based therapies in skeletal regeneration. Borrowing from an approach used to isolate hematopoietic stem cells (HSCs), the ASC subset can similarly be enriched based on cell surface markers using FACS. However, heterogeneity may persist even within a specific subset of sorted ASCs. While stem cell populations are known to be heterogeneous, the functional consequences of this heterogeneity have not been fully elucidated. The problem of undefined heterogeneity within stem cells must be overcome before they can be used effectively for therapeutic

Fig. 12.7 Overview of adipose-derived stromal cell harvest process. Liposuction aspirate (left) is digested, and then centrifuged to pellet the stromal vascular fraction (middle), and then plated in 10 cm dishes for expansion (right). ASCs, adipose-derived stromal cells; FBS, fetal bovine serum; PBS, phosphate-buffered saline; PCN, penicillin.

Fig. 12.8 Fluorescence-activated cell sorting (FACS) can be used to separate cells based on cell surface receptors. The goal would be to use these surface receptors to identify cells that are more likely to differentiate down a specific lineage. Here, FACS is used on a heterogeneous human adipose-derived stromal cell (ASC) population to isolate an osteoprogenitor population.

applications. The first step towards understanding this heterogeneity is to elucidate the gene expression profiles of these complex cells. This can be accomplished through single cell microfluidic technology (Fig. 12.9), which permits precise mixing of nanoliter quantities of quantitative PCR reagents to perform transcriptional analysis across individual cells.

Fig. 12.9 Fluorescence-activated cell sorting (FACS) can be used to isolate cells on a single cell level. Subsequently, human adipose-derived stromal cells can be studied on a single cell level to delineate further the transcriptional properties of each cell. PCR, polymerase chain reaction.

Methods of ASC delivery

Much remains unknown regarding the optimum method for delivering ASC therapy. A significant and growing number of studies have examined the intravenous (IV) administration of ASCs. Such studies have investigated the natural distribution of ASCs following IV injection. Interestingly, most organs show uptake of ASCs after administration, including bone and bone marrow tissues with some studies also showing long-term persistence within the host without oncogenic transformation.^{74–76} Studies have also examined IV injection of ASCs for repair of the liver,⁷⁵ heart,⁷⁷ endothelium,⁷⁸ and even olfactory epithelium.⁷⁹ An emerging area of investigation involves IV administration of ASCs for autoimmune and inflammatory disorders, such as experimental colitis and abdominal sepsis,^{80–82} muscular dystrophy,⁸³ experimental arthritis,⁸⁰ and encephalomyelitis.⁸⁴ Two provocative case studies have also been published showing beneficial outcomes of IV-delivered ASCs in humans: the first in rheumatoid arthritis, and the second in chronic autoimmune thrombocytopenia,^{85,86} indicating that IV ASCs may be a safe and beneficial future therapeutic modality.

In vitro: protocols on differentiation

Osteogenic differentiation (Fig. 12.10)

For osteogenic differentiation, cells should be plated in a six-well plate at a density of 100 000 cells per well, in 12-well plates at a density of 50 000 cells per well, or in a 24-well plate at 25 000 cells per well. After attachment, ASCs are treated with osteogenic differentiation medium (ODM) containing Dulbecco's modified eagle medium (DMEM), 10% FBS, 100 µg/mL ascorbic acid, 10 mM β-glycerolphosphate, and 100 IU/mL penicillin/streptomycin. This differentiation medium can be enhanced with the supplementation of several cytokines, such as insulin-like growth factor, platelet-derived growth factor (PDGF), or BMP-2 to stimulate increased osteogenesis.^{87,88} ODM should be replenished every 3 days.

Early and late osteogenic differentiation have been defined at time points that differ across species. Whereas mASCs undergo early osteogenesis by day 7 and late osteogenesis by day 14, hASCs undergo much more robust osteogenesis with early osteogenesis by day 3 and late osteogenesis by day 7. To assess osteogenic differentiation, RNA from ASCs

Fig. 12.10 Potential clinical uses for liposuction-acquired fat. Adipose-derived stromal cells (ASCs) are harvested by liposuction (left), cultured *in vitro* with differentiation medium (middle) to bone, and subsequently utilized for reconstructive procedures treating a myriad of diseases (right).

can be analyzed. Specific gene markers of osteogenic differentiation include osteocalcin (*OCN*), osteopontin (*OPN*), runt-related protein-2 (*Runx2*), collagen Ia (*COL1A*), and alkaline phosphatase (*ALP*). *ALP* staining and quantification can also be performed on day 3 of differentiation to assess early osteogenic activity (Fig. 12.11). Subsequently, late osteogenic activity can be assessed at day 7 of differentiation by alizarin red staining, which detects extracellular mineralization.

Adipogenic differentiation (Fig. 12.12)

To stimulate differentiation of ASCs towards mature adipose tissue, cells are seeded in a similar density as described for osteogenic differentiation. Adipogenic differentiation medium, which contains 10 $\mu\text{g/mL}$ insulin, 1 μM dexamethasone, 0.5 mM methylxanthine, and 200 μM indomethacin, is added to the cells. At 3 days, the medium should be replaced with 10 $\mu\text{g/mL}$ insulin. Differentiation can be assessed by oil

ASCs are harvested by liposuction (left), cultured *in vitro* with differentiation medium (middle) to fat, and subsequently utilized for reconstructive procedures treating soft-tissue defects (right).

red O staining and quantification or gene analysis. Specific genes expressed by adipose tissue during differentiation include *GCP1*, lipoprotein lipase (*LPL*), and peroxisome proliferation-activated receptor γ (*PPAR\gamma*; Fig. 12.13).

Chondrogenic differentiation

Chondrogenic differentiation is difficult to perform in monolayer and is thus performed using micromass cell droplets. Each 10 mL droplet contains 100,000 cells, which are seeded in culture dishes and allowed to form cell aggregates and substratum at 37°C for 2 hours. Chondrogenic medium includes DMEM, 1% FBS, 1% penicillin/streptomycin, 37.5 mg/mL ascorbate-2-phosphate, ITS (insulin, human transferrin, and selenous acid) premix, and 10 ng/mL transforming growth factor- β_1 (*TGF- β_1*). This medium is carefully added around the cell aggregates. By 24 hours, the aggregates should coalesce and become spherical. Micromasses are fixed with 4% paraformaldehyde/4% sucrose and embedded at day 3 and day 6 for histological analysis. Alcian blue allows for staining of chondrogenic tissues and glycosaminoglycan assays allow for quantification of chondrogenesis. Subsequent gene analysis can be performed using chondrogenic gene analysis such as *SOX-9*, aggrecan, and collagen II.

In vivo model

Nude athymic mouse 4 mm calvarial defect

To translate *in vitro* findings to the clinical realm, robust *in vivo* data must be obtained to demonstrate the osteogenic

Fig. 12.13 Adipocyte differentiation is associated with expression of lipoprotein lipase (LPL), peroxisome proliferator-activated receptor ($PPAR\gamma$), and enhancer-binding proteins (EBPs).

capacity of ASCs. *In vivo* models should include large immunocompetent animals such as sheep⁸⁹ and dogs,^{90,91} as well as smaller immunocompromised animals such as rabbits,⁹² rats,⁹³ or mice.²⁸ Though several models exist to determine *in vivo* osteogenic healing, we prefer the nude mouse model as it is reliable and easily reproducible. Immunocompromised animals such as nude athymic mice allow scientists to assess the effect of ASCs on an area while decreasing the innate immune response to xenotransplanted cells that can confound results. Mice are readily available in large quantities and can be studied by most small animal imaging technologies such as micro-computed tomography (micro-CT), micro-positron emission tomography (micro-PET), and bioluminescent imaging (BLI). Mice, however, heal wounds rapidly and effectively and thus scientists must demonstrate that any result is superior to the animal's baseline healing capacity. One way to demonstrate an effect is to create a defect so large that it overwhelms the animal's innate ability to heal the wound. This large defect is referred to as "critical-sized" and does not heal even over time. An example of this type of defect that we have utilized in an *in vivo* model is a 4 mm defect in the parietal bone of a nude athymic mouse.⁷²

Non-healing, critical-sized (4 mm) calvarial defects can be created in the right parietal bone of adult male CD-1 nude mice using a high-speed dental drill. After cleaning the surgical site with Betadine, an incision is made just off the sagittal midline to expose the right parietal bone. The pericranium is then removed using a sterile cotton swab. Using diamond-coated trephine bits and saline irrigation, unilateral full-thickness critical-sized calvarial defects are created in the non-suture-associated right parietal bone. It is important that the dura mater be left undisturbed as studies, including a 2011 study by Levi *et al.* suggest that cell-cell interactions between dura mater and engrafted ASCs may be crucial in stimulating osteogenic repair (Fig. 12.14). In preparation for implantation, scaffolds can be seeded with hASCs 24 hours prior to implantation. For scaffold creation, apatite-coated PLGA scaffolds were fabricated from 85/15 poly(lactic-co-glycolic acid) by solvent casting and a particulate leaching process. Briefly, PLGA/chloroform solutions were mixed with 200–300 μ m diameter sucrose to obtain 92% porosity (volume fraction), and compressed into thin sheets in a Teflon mold. After freeze-drying overnight, scaffolds were immersed in ddH₂O to dissolve the sucrose, and gently removed from the Teflon plate for disinfection and drying.

For apatite coating, simulated body fluid (SBF) solution was prepared by sequentially dissolving CaCl₂, MgCl₂·6H₂O, NaHCO₃, and K₂HPO₄·3H₂O in ddH₂O. Solution pH was lowered to 6 by adding 1 M hydrochloric acid to increase

solubility. Na₂SO₄, KCl, and NaCl were added and the final pH was adjusted to 6.5 (SBF 1). Mg²⁺ and HCO₃⁻ free SBF (SBF 2) was prepared by adding CaCl₂ and K₂HPO₄·3H₂O in ddH₂O and pH was lowered to 6. KCl and NaCl were added and the final pH was adjusted to 6.8. All solutions were sterile-filtered through a 0.22- μ m polyethersulfone (PES) membrane (Nalgene, NY). The obtained PLGA scaffolds were incubated in SBF 1 for 12 hours and switched to Mg²⁺ and HCO₃⁻ free SBF 2 for another 12 hours at 37°C under gentle stirring. Coated scaffolds were washed with ddH₂O to remove excess ions and lyophilized prior to use.

We found 150 000 cells/scaffold to be optimal in our laboratory.⁷³ The hASCs to be seeded onto each scaffold are first suspended in 25 μ L of growth media and placed onto the scaffold for 30 minutes. The scaffold is subsequently submerged in 100 μ L of growth media for 12 hours of incubation. Before implantation, cell-seeded scaffolds should be rinsed in sterile PBS to prevent transfer of medium-derived growth factors.

Clinical correlates

Recent case studies have focused on the use of hASCs to replace bone loss.⁹⁴ In case reports, defects of the calvaria,⁹⁵ maxilla,⁹⁶ and mandible⁹⁷ have either healed or been enabled to heal more rapidly with the use of hASCs. Such reconstructions eliminate the need for alloplastic materials and thus reduce the risk of infection, breakdown, or rejection. Despite increasing evidence from translational research, there is a paucity of data defining the mechanisms through which hASCs influence an osseous defect. Do hASCs directly form bone to heal a skeletal defect? Or do engrafted hASCs function as efficient factories to produce potent pro-osteogenic

Fig. 12.14 A 4-mm non-healing critical-sized defect in the right parietal bone of a CD-1 nude athymic mouse.

cytokines? In the case of our calvarial defect model, careful examination of calvarial defects engrafted with ASCs yields profitable insights into the potential derivation of healing. For example, bone is often observed to mineralize from the edges of a cranial defect inwards, which suggests that the host calvarium may contribute to the bony regenerate. Concurrently, small, isolated islands of bone are often observed early postoperatively, which suggests either contribution from engrafted ASCs or from host dura mater (another source of significant osteogenic progenitors).^{98–100} Finally, uniform and thorough healing of hASC-engrafted defects suggests that primary osseous healing is derived from the engrafted donor cells themselves. It is likely that all three cell types (donor ASCs, host calvarial osteoblasts, and host dura mater) contribute to bony healing.

Future direction of tissue engineering using ASCs

We believe that major breakthroughs in aesthetic and reconstructive surgery using autologous tissue will not come by incremental improvements to technical aspects such as liposuction cannulas or injection syringes. Instead, novel cell-based strategies must be explored to identify and isolate specific fat precursors from hASCs and to coordinate the physiologic induction of adipose tissue differentiation in a biomimetic environment *in vivo* (Fig. 12.15). However a significant gap exists between the current knowledge regarding ASC biology and their future translation to clinical use. First, the safety of hASCs must be determined. Potential oncogenic transformation must be inhibited so that tumors of mesodermal origin are not produced after cell engraftment.⁷⁶

hASC-seeded biomaterial constructs may constitute an optimal delivery method for autologous fat transfer by facilitating the assembly of natural three-dimensional adipose, cartilage, or bone tissues.¹⁰¹ Our ultimate translational goal is to harvest subcutaneous adipose tissue, isolate ASCs, and implant these cells on an osteoconductive and/or osteoinductive scaffold into the skeletal defect within the course of a single operative procedure without leaving the operating room (Fig. 12.16).

Bone marrow mesenchymal stem cells

Definitions

Bone marrow MSCs are multipotent adult stem cells that have been shown to differentiate into a variety of cell types, including adipocytes, chondrocytes, osteocytes, skeletal myocytes, and cardiomyocytes. Numerous studies have documented MSC plasticity, immunomodulatory properties, and potential for use in tissue engineering strategies. MSCs have also been found to be recruited to sites of injury, where they may participate in the body's own natural system of tissue repair. These findings highlight the enormous potential for MSCs in clinical use for an increasing range of medical disorders. While some debate remains over the effect of MSCs in various disease states, their prospects for use as an "off-the-shelf" biological therapeutic remains a tangible goal.

The role of MSCs within bone marrow has been debated, with work by Prockop and others helping to elucidate functions both intrinsic and extrinsic to the bone.^{7,102} By infusing

Fig. 12.15 Utilization of adipose-derived stromal cells (ASCs) to heal a skeletal defect. **(A–C)** Micro-computed tomography images of a 4-mm critical-sized mouse parietal bone defect in nude CD-1 mice. **(A)** Without either a scaffold or ASCs, this defect will not heal by 2 weeks. **(B)** Scaffold only. Wounds treated with scaffold alone also show minimal healing. **(C)** Scaffold with ASCs. Significant re-mineralization is observed after only 2 weeks post-injury in wounds treated with ASC-seeded scaffolds.

genetically marked MSCs into isogenic mice, studies revealed a distribution of these cells to various locations, including cortical and cancellous bone, cartilage, spleen, thymus, lung, and liver.⁷ MSCs thus demonstrate the ability to circulate and participate in normal cellular turnover even outside of hematopoietic tissues.

Current concepts and research

In recent years, the potential use of MSCs in therapeutic modalities for tissue repair has become increasingly promising. As such, a number of studies have focused on phenotypically characterizing these cells both *in vitro* and *in vivo*. The initial isolation of MSCs exploited their ability to adhere to plastic. However, many of the clones isolated by Friedenstein's method proved incapable of osteogenic differentiation.^{103,104}

This suggested that a considerably heterogeneous population of cells exists within the marrow stroma. Percoll gradients, as employed by Pittenger *et al.*,¹³ Caplan,¹⁰⁵ and Haynesworth *et al.*,¹⁰⁶ allowed for a more homogeneous population of MSCs to be harvested, as confirmed by flow cytometric analysis of cell surface antigens. Alternative methods to obtain higher degrees of homogeneity have also been attempted, including culturing MSCs in low oxygen tension.^{107,108} Perhaps the most rigorous means by which to define MSCs has been through the use of cell surface antigens expressed *in vitro*. The International Society for Cellular Therapy announced

Fig. 12.16 Ultimate clinical translational goal: taking patient to the operating room and harvesting a multipotent, self-renewing cell population such as human adipose-derived stromal cells (hASCs), and then placing them on a scaffold for reconstruction of a tissue defect. FACS, fluorescence-activated cell sorting.

specific criteria to define bone marrow MSCs in 2006.¹⁰⁹ Based on these criteria, MSCs are required to be plastic-adherent when maintained in standard culture conditions and to express CD73 (ecto 5'-nucleotidase), CD90 (Thy-1), and CD105 (Endoglin) while lacking expression of CD45 (protein tyrosine phosphatase), CD34 (hematopoietic cluster differentiation molecule 34), CD14 (macrophage/neutrophil cluster differentiation molecule 14), CD19 (follicular dendritic cell/B-cell cluster differentiation molecule 19), and human leukocyte antigen (HLA)-DR. Furthermore, MSCs must be capable of differentiation into adipocytes, chondroblasts, and osteoblasts *in vitro*. While these criteria continue to evolve, they have served as a minimum standard for more recent investigations.

While the *in vitro* characterization of MSCs has progressed, phenotypic delineation of these cells *in vivo* has advanced at a much slower pace and collective data remain far from complete. More recently, investigators enriched the STRO-1 fraction through additional positive selection for CD106 (vascular cell adhesion molecule-1: VCAM-1) and CD146 (melanoma cell adhesion molecule), obtaining a purified fraction capable of self-renewal and multipotent differentiation.¹¹⁰ These findings lend further support to the notion that MSCs function as an *in vivo* stem cell source for derivation of mesenchymal tissue.

The lineage of MSCs and HSCs has also been carefully evaluated by investigators looking to determine whether MSCs and HSCs exist as different populations within bone marrow. Through sex-mismatched HLA-identical bone marrow allografts, researchers have demonstrated that marrow-derived stromal cells are exclusively host-derived

while HSC-derived macrophages originate from donors.¹¹¹ This finding indicates that MSCs existing within the stromal fraction are distinct from hematopoietic cells. Contemporary models thus identify at least two types of stem cells within the bone marrow, with HSCs giving rise to hematopoietic cell types and osteoclasts, while MSCs differentiate into a multitude of mesenchymal lineages. Furthermore, it is widely believed that MSCs are derived from mesoderm and that, as these cells stain positive for angiopoietin-1, they likely reside with pericytes located along the walls of sinusoidal blood vessels in bone marrow.^{112,113}

Recent investigations have identified an extraordinary property of MSCs with important therapeutic implications. Although still poorly understood, MSCs have been found to possess immunomodulatory properties.^{114–119} Baseline expression of MHC class I proteins has been detected in MSCs while MHC class II proteins are entirely absent.¹²⁰ This particular profile has been associated with non-immunogenic conditions, thus potentially allowing for MSC transplantation into allogeneic hosts without the requirement of immunosuppressive therapy.¹²¹ Even more surprising, MSCs have been found to be capable of modulating T-cell function.^{114,115,117,119} In co-culture conditions, MSCs have been shown to decrease expression levels of pro-inflammatory cytokines, including tumor necrosis factor-alpha, interferon-gamma, interleukin-4, and interleukin-10 in dendritic cells and helper T cells.¹¹⁵ MSC secretion of interleukin-1 receptor antagonist has also been reported to contribute to overall MSC-mediated immunosuppression.¹²² From a clinical perspective, these properties may one day be exploited for treatment of conditions such as graft-versus-host disease and autoimmune disorders.^{121,123}

***In vitro*: protocols on tissue harvest and differentiation**

Contemporary technologies to harvest and culture MSCs still utilize the same fundamental property of adherence to plastic employed by Friedenstein *et al.* over 40 years ago.⁸ More recently, investigators have incorporated the use of density gradients to increase homogeneity and eliminate unwanted cell types present in marrow aspirate.¹³ Human MSCs are commonly harvested from the iliac crest.¹²⁴ Murine MSCs, in contrast, can be harvested from either fibula or tibia by first flushing the marrow contents out with a 27G syringe.¹²⁵ Harvested bone marrow is then placed in an aqueous solution of highly branched hydrophilic polysaccharides. By centrifuging for 30 minutes, four layers become visible. Red blood cells may be found in the bottom layer, polysaccharide solution may be found in the second layer, the third layer contains the majority of mononuclear cells, and the top layer contains primarily acellular medium. It is the third layer (mononuclear cells) that is isolated, re-centrifuged, and plated on to plastic culture dishes. MSC colonies may often be observed to form on these dishes after 6–8 days of *in vitro* culture.

Lineage-specific culture conditions that induce differentiation of MSCs into adipocytes, chondrocytes, osteoblasts, and myoblasts have been well described. Adipogenic differentiation can be induced by treatment of MSCs with 1-methyl-3-isobutylxanthine, dexamethasone, insulin, and indomethacin.¹³ Fat accumulation can be readily appreciated histologically by the formation of lipid-rich vacuoles within cells. In addition, differentiated MSCs have been shown to express various markers of adipogenic differentiation, including *PPAR* γ 2, *LPL*, and fatty acid-binding protein aP2 (see Fig. 12.13). To promote chondrogenic differentiation, MSCs are cultured serum-free in a pelleted “micromass” with TGF- β ₃.¹³ A proteoglycan-rich extracellular matrix can be observed along with expression of type II collagen after 2 weeks, both of which are typically found in articular cartilage. Osteogenic differentiation of MSCs can be accomplished with the same components as described in the previous section on ASCs. Finally, culture of MSCs with dexamethasone and hydrocortisone has been shown to induce expression of key regulatory factors for myogenic differentiation, including *MyoD*1 and myogenin.¹²⁶

***In vivo* models**

The ability for MSCs to differentiate along several lineages has made these cells excellent candidates for the repair and regeneration of many tissues. The multipotency of MSCs, along with their ease of isolation and expansion potential, has led to a variety of preclinical studies evaluating their use in treating cardiovascular disease, central nervous system injury, diabetes, and bone/cartilage regeneration.

Cardiovascular disease remains one of the leading causes of morbidity and mortality worldwide, accounting for nearly 20 million deaths annually.¹²⁷ Contemporary approaches to treatment have centered on preservation of myocardium through pharmacologic therapy and revascularization. The ability for MSCs to undergo transdifferentiation along a cardiomyogenic lineage has sparked recent interest in their application for post-infarct myocardial regeneration.¹²⁸ Importantly, *in vivo* studies have demonstrated that injected

MSCs preferentially migrate to sites of inflammation, thereby allowing for their potential participation in repair of injured cardiac muscle.¹²⁹ Myocardial ischemia may promote release of chemo-attractive factors, increase vascular permeability, and enhance expression of adhesion proteins to allow for proper homing of MSCs. A 2015 randomized, double-blind, placebo-controlled trial conducted by Mathiasen *et al.* found that intra-myocardial injections of MSCs decreased left ventricular end systolic volume (LVESV) in patients suffering from New York Heart Association heart failure classes II–III with ejection fraction <45%. In contrast, patients treated with placebo had increased LVESV at six months follow-up. No adverse effects were identified during the course of the study. They concluded that intra-myocardial injections of autologous culture-expanded MSCs were safe for clinical use and improved myocardial function in patients with severe ischemic heart failure.¹³⁰ How these cells truly act at post-infarct sites, however, remains controversial.

Like myocardial infarction, injury to the central nervous system has also contributed to significant death and disability worldwide. As investigators have shown MSCs to be capable of undergoing transdifferentiation into ectoderm-derived neuronal tissue, MSC use in various animal models of stroke has yielded provocative findings.¹³¹ Several studies have demonstrated that injected MSCs can migrate to sites of stroke injury and differentiate into cells expressing neuronal markers.^{132–134} Preliminary reports in rats have also shown that MSCs may potentially restore damaged neurons.^{133,134} From a functional perspective, improved sensorimotor function has been detected following injection of MSCs into sites of cortical ischemia.¹³⁵

The treatment of diabetes has been another field where use of MSCs has provided some promising results. Presently, type 1 diabetes may be partially reversed through the replacement of functional pancreatic β cells. Unfortunately, islet cell transplantation has been limited by immune rejection and continued autoimmune-mediated destruction.¹³⁶ The scarcity of donor islet cells further obstructs treatment of this disease. The potential ability of MSCs to modulate the immune system and undergo *in vitro* β -cell transdifferentiation has led to several preclinical investigations employing these cells in animal models of diabetes.^{136–139} As with cardiac ischemia and stroke, however, the true role of MSCs in ameliorating hyperglycemia remains controversial. Introduction of human MSCs into immunocompromised diabetic mice was found to upregulate only mouse insulin production. This suggests that MSCs promote regeneration of endogenous islets but do not undergo transdifferentiation and integration into the host pancreas.¹³⁹ Nonetheless, these findings indicate that MSCs may one day represent a viable therapeutic option for the treatment of type 1 diabetes.

The potential use of MSCs most germane to the field of plastic and reconstructive surgery remains the utilization of these cells in bone and cartilage regeneration. Bone homeostasis represents a careful balance between bone production by mesenchymal lineage osteoblasts and bone resorption by hematopoietic lineage osteoclasts.¹²¹ MSCs potentially alter this balance through the modulation of receptor activator of nuclear factor- κ B ligand (RANKL) and osteoprotegerin expression.¹²¹

It has been suggested that a loss of MSC function may contribute to reduced bone regeneration with age.¹⁴⁰ MSCs

have thus been evaluated as potential cellular building blocks for tissue engineering strategies. Using a canine femoral critical-sized defect model, investigators have shown MSCs to be capable of regenerating bone when loaded onto a hydroxyapatite-tricalcium phosphate cylinder.^{90,91,141} Sixteen weeks after introduction of MSCs, histological analysis revealed new bone spanning the entire defect.⁹¹ In addition, both autologous and allogeneic MSCs were found to yield equivalent results with no lymphocytic infiltration or antibody formation noted when leukocyte antigen-mismatched allogeneic cells were implanted.⁹¹

Vascular composite allotransplantation (VCA), including osseous defects, is another growing area of interest in reconstructive surgery. Interestingly, MSCs have been shown in animal models to increase regulatory T-cell levels and prolong survival of immunogenic skin-bearing VCA osseous grafts when combined with a short course of immunosuppression.¹⁴²

Apart from the appendicular skeleton, investigators have also studied the use of MSCs in promoting bone formation for the spine. Spinal fusion remains the last resort for degenerative disc disease and over 300 000 cases are operated on annually in the US.¹²¹ Current research has focused on improvement of spinal fusion through the combination of autologous bone marrow with synthetic scaffolds and cytokine therapy. MSCs implanted on Matrigel and placed into the lumbar fusion bed of rats have been shown to result in a greater rate of successful fusion compared to animals receiving only mixed-marrow stromal cells.¹⁴³ Kai *et al.* reported similar results in rabbits using a combination of MSCs, calcium phosphate ceramic blocks, and recombinant human BMP-2.¹⁴⁴ These results suggest that MSCs may be a suitable replacement for more traditional methods currently employed in iliac crest bone grafting. MSCs may also allow for greater mature osseous tissue formation at earlier time points following spinal fusion.

Repair and regeneration of cartilage remain another challenging problem where MSCs may yield more compelling strategies than those currently available. The ability to treat damaged cartilage and osteoarthritis is currently quite limited with prosthetic joint replacement representing the best contemporary solution. Preclinical trials in goats, however, have shown MSCs to promote cartilage regeneration in knee joints.¹⁴⁵ Following surgical induction of osteoarthritis by excision of the medial meniscus and resection of the anterior cruciate ligament, Murphy and colleagues found that a single injection of MSCs suspended in dilute sodium hyaluronan could result in reduction of articular cartilage degeneration, osteophytic remodeling, and subchondral sclerosis.¹⁴⁵ These findings have also been observed in a mouse model for human rheumatoid arthritis where allogeneic MSCs introduced intraperitoneally were found to prevent occurrence of severe irreversible damage to cartilage and bone.¹⁴⁶ Rather than directly providing a cellular contribution to cartilage formation, in this instance MSCs were thought to modulate immune responsiveness and expression of inflammatory cytokines.¹⁴⁶

Clinical correlates

The last two decades of research with MSCs in both *in vitro* culture and *in vivo* animal models has allowed scientists to

begin incorporating these cells into clinical trials for an ever-increasing range of potential medical disorders.^{121,123} MSCs have been proposed for the treatment of a wide variety of diseases and patients have already begun enrolling in industry-sponsored studies (Osiris Therapeutics, Waltham, MA) that investigate the use of these cells in graft-versus-host disease, Crohn's disease, and type 1 diabetes. The FDA has also approved the study of autologous MSCs in middle cerebral artery acute stroke treatment. To date, the most prominent application of MSCs in clinical trials has been their use in ischemic heart disease.

Following ischemic insult to the myocardium, reperfusion may salvage large regions of viable muscle, but this is often incomplete, resulting in a process of adverse left ventricular remodeling.¹⁴⁷ As previously noted, preclinical trials have shown that autologous MSCs improve cardiac function modestly either through transdifferentiation or elaboration of trophic factors capable of stimulating endogenous reparative mechanisms.^{148,149}

Similar to ischemic cardiomyopathy, MSCs have also proven to be efficacious in early clinical studies involving skeletal disease. Long-bone distraction osteogenesis is an emerging field in which MSCs have been found to promote improved healing and faster recovery rates.¹⁵⁰ In 17 patients undergoing distraction, injection of MSCs along with platelet-rich plasma into the callus during both lengthening and consolidation phases resulted in accelerated mature bone formation and a reduction in the incidence of complications.^{151,152} Horwitz and colleagues have also investigated the use of MSCs in the treatment of osteogenesis imperfecta, a genetic disorder of type I collagen resulting in fragile bones and skeletal deformities.^{153–155} While there is no current cure for osteogenesis imperfecta, preliminary reports have shown MSCs to be successful in enhancing bone formation in these patients.¹⁵⁴ Children receiving two infusions of allogeneic MSCs were noted to demonstrate engraftment of these cells in multiple sites, including bone and skin. Importantly, accelerated growth velocity was appreciated during the first 6 months following treatment with no associated complications.¹⁵³ These findings reveal that MSCs may be safely administered to children and when injected can localize to genetically defective tissues. Furthermore, MSC therapy has been demonstrated to be safe and effective in small numbers of patients treated with MSCs to ameliorate clinical symptoms of osteoarthritis. The 2015 study found that in patients with severe knee osteoarthritis, the knee injected with MSC had better function at 5 years compared to the knee that was not injected.¹⁵⁶ Another 2015 study expanded on this finding by demonstrating long-term safety and efficacy of intra-articular MSC injection in patients with different osteoarthritic joints (such as hip, knee, and ankle osteoarthritis).¹⁵⁷ In summary, while the human data at present is promising, further studies are needed with larger sample sizes and longer follow-up periods to confirm the clinical benefit and safety of MSC use in bone regeneration. There are myriad clinical trials currently underway to address these important questions, with an excess of 140 clinical trials at various stages of investigation recorded in the US at present.

The breadth of clinical trials involving MSCs is rapidly expanding, as studies have shown these cells to possess a strong propensity to ameliorate a wide range of tissue deficits secondary to injury or disease.

Tissue-specific stem cells

Definitions

Adult stem cells are undifferentiated cells found in almost all tissues and organs after embryonic development¹⁵⁸ and have the capacity for both self-renewal and differentiation into a restricted number of specialized cell types of the tissue or organ in which they are found. Their major function is to maintain homeostasis and ensure that tissue damage resulting from various forms of insult or injury is repaired. It has been hypothesized that defects in adult stem cell function may be responsible for a range of diseases. A study of adult stem cell function could therefore reveal important biological mechanisms that could be exploited for therapeutic purposes.¹⁵⁹

Although rare, adult stem cells serve a critical function within the hierarchical organization of complex tissues and organs. They give rise to replacement cells to maintain tissue integrity throughout development. A model of coexisting quiescent and active progenitor subpopulations has been proposed to describe adult stem cells with different cell cycle states.¹⁶⁰ It is hypothesized that they exist in tightly regulated zones to ensure that differentiated cells can be rapidly repopulated while keeping a quiescent back-up system to maintain the longevity of adult stem cell pools. Another concept which has been studied in adult stem cells is transdifferentiation, or the ability of lineage-directed stem cells to differentiate into tissues or organs from another embryonic lineage.¹⁶¹ For example, studies in mice have demonstrated the ability of bone marrow stem cells to differentiate into multiple cell types.

Current concepts and research

Skin

Mammalian skin is a widely available and readily accessible tissue for the study of adult stem cell function. Gene expression studies have identified critical regulators of epithelial stem cell function, including Wnt/beta-catenin, BMP, notch, and Hedgehog pathways.¹⁶² Furthermore, numerous subtypes of epithelial progenitors have recently been identified and contribute to different skin compartments containing specific resident epithelial stem cells, such as the hair follicle, sebaceous glands, and the interfollicular epidermis (Fig. 12.17).¹⁶³ Hair follicle stem cells are located in the bulge region and cycle slowly under normal conditions. However, following injury they rapidly activate and migrate outwards toward the region of epithelial damage.¹⁶⁴

These epithelial stem cells are located in discrete skin compartments but have common features, which may reveal unifying mechanisms in normal homeostasis. They all express K5, K14, and delta Np63, are adjacent to an underlying basement membrane, and utilize many of the same regulatory signaling pathways.¹⁶⁵ The complex skin environment also houses putative melanocyte stem cells involved in the graying of hair¹⁶⁶ and dermal pericytes which have been implicated as important stem cell regulators of skin regeneration.¹⁶⁷

Many of the mechanisms underlying skin embryogenesis are recapitulated later in adult life to maintain skin homeostasis.¹⁶² Several models have been proposed to explain the balance of stem cell populations and function. One such model describes asymmetric versus symmetric cell division. Symmetric cell

Fig. 12.17 Cells surrounding the hair follicle traffic to a wound site. IFE, interfollicular epidermis; IRS, inner root sheath; MSCs, mesenchymal stem cells; ORS, outer root sheath.

division describes the generation of two daughter cells that eventually acquire the same differentiated fate. Asymmetric division describes the process whereby a stem cell produces one daughter cell with a stem cell fate and another daughter cell destined for differentiation. These models are not mutually exclusive and are both thought to play an important role in the maintenance of skin stem cell populations.¹⁶⁸

Bone

Osteoblasts are derived from bone marrow MSCs and their differentiation pathways have been well studied. These cells form bone, regulate bone growth and remodeling, and differentiate into mature osteocytes in response to stimuli such as mechanical loading, hormones, and cytokines.¹⁶⁹ A delicate balance is maintained with their osteoclast counterparts, which resorb bone and are derived from monocyte/macrophage precursors. During adult osteogenesis, bone formation proceeds through two different pathways: intramembranous ossification (e.g., skull) or endochondral ossification (e.g., long bones). The former occurs directly from MSC condensation while the latter involves an intermediate MSC-mediated cartilage formation step followed by replacement with bony matrix (Fig. 12.18).¹⁷⁰

Osteoblast differentiation is regulated by several major signaling pathways such as Wnt, BMP, FGF, Hedgehog and transcription factors such as Runx2, Osterix, ATF4, and TAZ.¹⁷¹ These signals determine the fate of skeletal lineage precursors and can be manipulated to induce bone regeneration. BMP-2, -4, and -7 have been successfully used to induce osteoblast differentiation and matrix formation *in vivo* and vehicles for BMP gene delivery such as plasmids and viruses have been effectively employed.¹⁷² Combination gene delivery has been

Fig. 12.18 Mesenchymal stem cell (MSC) condensation into an osteoblast as in intramembranous ossification.

successful and is thought to recapitulate more closely the signaling environment *in vivo*, providing a synergistic stimulus for bone formation. This sensitization effect has been demonstrated with combinations of BMPs, vascular endothelial growth factor (VEGF), RANKL, and Runx2 delivery.¹⁷²

Blood vessels

Regulated blood vessel development in response to tissue injury or ischemia is critical for maintenance of healthy tissues. Dysfunction in this neovascularization process often results in disease.¹⁷³ For example, adequate wound healing requires a robust vascular response to deliver immune cells and metabolic substrates necessary for tissue regeneration.¹⁷⁴ In addition, a coordinated pattern of neovascularization signaling and stem cell recruitment is essential for normal organ development during embryogenesis,¹⁷⁵ as well as for tumor growth and metastasis.¹⁷⁶ During embryogenesis, mesoderm-derived angioblasts organize via vasculogenesis to form blood vessels.¹⁷⁷ It was initially believed that all subsequent blood vessel growth occurred through sprouting of pre-existing endothelial cells in a process known as angiogenesis

Fig. 12.20 Muscle satellite cells located between muscle fibers and their basement membrane.

(Fig. 12.19).¹⁷⁸ However, it has been discovered that the vascular programming evident during embryonic development is recapitulated in various postnatal states during a process known as adult vasculogenesis (see Fig. 12.19).¹⁷⁹

Endothelial precursor cells (EPCs), which are bone marrow-derived progenitor cells that participate in adult vasculogenesis, were first identified by Asahara *et al.*¹⁸⁰ These cells are recruited to the site of ischemia and divide to form syncytial masses, which tubularize and canalize to form a patent vascular network.¹⁸¹ Pericytes, which retain the pluripotency of MSCs,¹¹² are also intimately involved in vascular morphogenesis. They reside at the interface between endothelial cells and the surrounding tissue and produce pro-angiogenic signals that regulate endothelial cell differentiation and growth.¹⁸² Through both direct physical interaction and paracrine signaling, endothelial cells and pericytes engage in complex crosstalk that is essential for normal vasculogenesis.¹⁸³

Muscle

Satellite stem cells were first described by Mauro in the 1960s as mononucleated cells situated between muscle fibers and their basement membrane (Fig. 12.20).¹⁸⁴ Though different modes of asymmetric cell division have been proposed to regulate satellite cell self-renewal,^{185,186} symmetric cell division is believed to play a major role in the response to muscle injury or when large amounts of myogenic cells are needed to replace missing or dysfunctional muscle mass.¹⁸⁶ Repair mechanisms are also thought to involve recruitment of neighboring satellite cells and circulating myogenic stem cells. In addition, satellite cell dysfunction has been proposed

Fig. 12.19 Sprouting of pre-existing endothelial cells in a process known as angiogenesis (left). Formation of new vessel from circulating endothelial progenitor cell known as vasculogenesis (right).

to underlie certain muscular diseases such as Duchenne muscular dystrophy, but this hypothesis requires further study.

The major components of the satellite cell niche are: the adjacent muscle fiber (including the mechanical, electrical, and biochemical signals which emanate from it), the basal lamina, and the microvasculature. These interrelated components regulate the activity of muscle stem cell populations and include calveolin-1, sphingomyelin, calcitonin receptors, the transmembrane protein Megf10, Notch signaling, and matrix components such as proteoglycans.¹⁸⁶

Peripheral nerve

Although peripheral nerves have the capacity to regenerate axons following injury, outcomes after repair remain poor due to direct neuronal damage, as well as chronic denervation of the distal end.¹⁸⁷ However, when denervated supporting Schwann cells are replaced with healthy ones at the site of injury, nerve regeneration is improved (Fig. 12.21). This suggests that cell-based therapies may have an important role in treating nerve injuries. Guenard *et al.* demonstrated that syngeneic Schwann cells could effectively improve nerve regeneration in rat sciatic nerve injuries.¹⁸⁸ Murakami *et al.* transplanted neural stem cells obtained from the hippocampus of rat embryos into sciatic nerve defects and demonstrated nerve regeneration after 8 weeks.¹⁸⁹ Mean number of myelinated fibers and fiber size were increased compared to controls.

Neurotrophic growth factors have also played an important role in experimental models of nerve repair. These include NGF, brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), NT-4/5, FGF, and PDGF, amongst others.¹⁹⁰ Neurotrophic growth factors are delivered through matrix/conduit release or mini-pump systems but bioavailability throughout the necessary regenerative time scales remains an issue.

Fig. 12.21 Schwann cell migration to peripheral nerve injury site to assist in repair.

Clinical correlates

Skin

Cell-based therapies have been used for decades in the treatment of burn injury. Autologous epidermal sheets have been grown *ex vivo* and re-implanted into patients with varying degrees of success.¹⁹¹ Bone marrow and fat-derived MSC therapies have proven useful for chronic wounds in the clinical setting, although these are mostly case reports.¹⁹² Dash *et al.* reported a randomized clinical trial using autologous bone marrow MSCs to treat chronic non-healing ulcers.¹⁹³ In this study, stem cell-treated patients demonstrated improvements in pain-free walking and reductions in ulcer size up to 12 weeks post-treatment.

Transplantation of HSCs from peripheral blood and bone marrow has also demonstrated engraftment of cells into skin.¹⁹⁴ Histological evaluation of skin specimens from sex-mismatched transplants showed that up to 7% of cells were XY-positive, indicating that circulating stem cells could differentiate into mature epithelium. However, another study with a similar sex-mismatched transplant design failed to show donor stem cell contribution to keratinocyte populations.¹⁹⁵ Badiavas and Falanga reported on 3 patients with chronic lower extremity wounds refractory to standard therapy who were treated with autologous bone marrow stem cells.¹⁹⁶ Complete wound closure was observed in all 3 patients and there was less wound fibrosis compared to pretreatment wound specimens. It appears that numerous adult stem cell populations can contribute to skin regeneration but the optimal combination of cells and signals remains unknown.

Bone

As previously mentioned, allogeneic bone marrow-derived stem cells transplanted with around 2% donor cell engraftment were shown to improve osteogenesis in three children with osteogenesis imperfecta.¹⁵⁴ Three months after treatment, all patients had increased total bone mineral content, growth velocity, and reduced frequency of bone fracture. In addition, MSCs have shown great promise in early clinical trials in the symptomatic improvement of osteoarthritis in multiple joints as described in a previous section,^{156,157} and osteonecrosis of the femoral head.^{197–199} For instance, a study published in 2015 by Daltro *et al.* found that autologous stem cell transplantation provided both pain relief and stopped the progression of osteonecrosis of the femoral head in patients with sickle cell disease. The focus of MSC therapy in currently active clinical trials include: articular cartilage resurfacing with MSCs in osteoarthritis, non-union of fractures, periodontal disease, and spinal fusion.

Blood vessels

Studies have demonstrated a strong correlation between clinical risk factors for cardiovascular disease and EPC function and quantities. Disease states such as diabetes, coronary artery disease, smoking, and hypercholesterolemia are known to affect EPCs adversely, prompting efforts to improve clinical outcomes through EPC augmentation.²⁰⁰ Direct injection of EPCs, as well as growth factors, such as granulocyte-macrophage colony-stimulating factor have been used with some success following cardiac ischemia. A

meta-analysis found that intracoronary bone marrow cell infusion is a safe way to administer EPCs and is associated with a minor improvement in left ventricular function at 3–6 months following acute myocardial infarction.²⁰¹

Muscle

Satellite cells have generally been incompatible with systemic administration and exhibit poor viability and migration when delivered intramuscularly. Thus, the therapeutic potential of muscle stem cells has focused more on progenitor populations derived from the endothelial lineage. These cells, which include mesoangioblasts, pericytes, and CD133+ cells, have significant myogenic potential and readily cross the endothelium, making intra-arterial delivery possible.¹⁸⁵ In animal models, these muscle progenitors have shown the ability to restore muscle function and to reconstitute the satellite stem cell compartment to varying degrees.²⁰² Numerous human trials for Duchenne muscular dystrophy demonstrated effective dystrophin production with the use of injected stem cells, but clinical benefits have not been observed.²⁰³ Clinical trials have also been conducted with muscle stem cells for ischemic heart disease and stress urinary incontinence, with mixed improvements in muscle function.²⁰⁴

Nervous system

Treating disorders of the central nervous system (CNS) has been one of the most challenging areas of modern medicine. Regenerative medicine using defined stem and progenitor cells offers the potential for neuroprotection (to prevent further cell loss) and/or neuronal replacement (to replace damaged or lost neurons). Both of these strategies can be envisioned in chronic neurodegeneration (i.e. age-related macular degeneration and Alzheimer's disease) and genetic neurodegeneration, as well as in injuries to the CNS (spinal cord injury, stroke, and traumatic brain injury).

A seminal finding in advancing regenerative medicine for neurological disorders was the demonstration that neurogenesis continues to occur in the adult human brain.²⁰⁵ This discovery, together with the identification and expansion of human neural stem cells,^{206,207} has led to a plethora of studies investigating neuroregeneration.^{206,208} One such human neural stem cell population is the HuCNS-SC, an adult tissue-specific stem cell, first characterized in 2000 by Stem Cells, Inc.^{209,210} Each HuCNS-SC bank is created from purified neural stem cells from a single fetal brain tissue at 16–20 weeks' gestation by prospective isolation using flow cytometry.²⁰⁶ Manufactured under cGMP standards, the company's HuCNS-SCs are purified, expanded in culture, cryopreserved, and then stored as banks of cells, ready to be made into individual patient doses when needed. Building on the promising animal studies,²¹¹ where evidence of engraftment, global CNS migration and multi-lineage differentiation (astrocytes, oligodendrocytes, and neurons) was demonstrated, these allogeneic cells were then tested in phase I/II clinical trials for specific CNS disorders based on neuroprotective and neuronal replacement strategies to determine safety and preliminary efficacy of HuCNS-SCs.^{206,212} As HuCNS-SCs have now been shown to engraft and survive long term,^{209,213} there is possibility of a durable clinical effect following single transplantation. In the multi-center study of spinal cord injury, seven patients received cell transplantation above and below the site of injury. In

addition to safety, 12-month data analysis also revealed sustained improvements in sensory function that emerged consistently around three months after transplantation and persisted until the end of the study. The patterns of sensory gains were confirmed to involve multiple sensory pathways and were observed more frequently in the patients with less severe injury. HuCNS-SCs were also shown to be safe and effective in the treatment of congenital neurodegenerative diseases.^{206,212} Further investigation is now underway with larger patient numbers, to build upon promising phase I/II clinical data.

Prospective clinical applications of stem cell therapy

Scaffolds for stem cell delivery

Stem cells exist in tightly controlled environmental niches and alterations in this microenvironment can dramatically modify their behavior and capabilities. Furthermore, they are often utilized in the setting of disease or injury where toxic signals that can impair their function are prevalent. Thus, strategies using biomaterial scaffolds are important to stem cell therapy as they help provide a controlled environment in which implanted cells can be protected from harmful stimuli. Biomaterial matrices can also be used to deliver genetic material and/or inductive biochemical cues, which allow for some degree of developmental control over the delivered stem cells (Fig. 12.22). In terms of tissue and organ regeneration, scaffolds provide the structural template on which to build new tissues and can thus be prefabricated based on their ultimate purpose. For example, more rigid scaffolds are much better

Fig. 12.22 Bioscaffold construct. Bioscaffolds can be tailored based on the stem cell type and small molecule utilized, as well as the protein type, peptide sequence, and matrix components.

suited for bone engineering, whereas soft flexible scaffolds are ideal for skin applications.

Scaffolds can be broadly separated into two categories: native or synthetic. Native scaffolds include those derived from living or cadaveric donors and can be autogenous, allogeneic, or xenogeneic. An excellent example of the utilization of such scaffolds is the treatment of massive burns with dermal substitutes derived from a wide range of human and nonhuman sources. Native matrices can be obtained through decellularization of tissues and whole organs. The matrices can then be seeded with exogenous therapeutic cells.^{214,215} These techniques include the use of physical/mechanical forces, chemicals, and enzymatic agents to remove cellular material with minimal disruption to the matrix.²¹⁶

Recently, there has been increased focus on “smart” biomaterials.²¹⁷ These materials incorporate peptide sequences capable of better mimicking the native cellular environment and can significantly modulate cell differentiation, adhesion, and proliferation.²¹⁸ Smart polymers may allow scaffolds to respond to temperature, pH, light, or ionic interactions with altered mechanical properties, hydrophobicity, collapse, or expansion.²¹⁹

Numerous studies have demonstrated the benefits of utilizing stem cell-scaffold constructs in regenerative medicine. For one, scaffolds provide a highly modifiable vehicle for inductive factors. Fang *et al.* utilized plasmid DNA loaded onto collagen sponges and demonstrated successful *in vivo* genetic manipulation of fibroblasts to induce bone formation in rats.²²⁰ In another study, poly(lactide-coglycolide) scaffolds loaded with DNA plasmid demonstrated enhanced cell transfection and matrix formation compared to naked plasmid injection alone.²²¹ Schek *et al.* found that bone formation was greater with hydrogel delivery of BMP-7-expressing adenovirus in mice compared to non-hydrogel controls.²²² While there are still considerable challenges facing the development of the ideal artificial scaffold, ongoing innovation has led to significant advances combining innovative scaffolding design with increased understanding of stem cell biology.²²³ Heightened awareness of the importance of scaffold topography and porosity, degradation rates, and incorporation of bioactive molecules has continued abreast of technological and stem cell advances.²²⁴ Three-dimensional printing strategies for scaffold manufacture have also accelerated personalized scaffold development, and one can envisage adaption of this computational technology to create effective personalized scaffolds for reconstructive surgery generated from 3D imaging in addition to scaffolds for stem cell delivery.^{223,224}

In summary, as researchers continue to unravel the complex signals and interactions that act to modulate stem cell behavior, advances in biomaterial techniques will be crucial to our ability to recapitulate with accuracy the various endogenous stem cell microenvironments.²¹⁷

Genetic induction therapies

Cell-based regenerative strategies are also critically dependent on the biochemical signaling environment. Exogenous administration of specific growth factors and cytokines can induce stem cell differentiation, which provides researchers with a powerful means of manipulating stem cell behavior

in vitro. Stem cells can also be coaxed down various paths of differentiation through gene transfer and cytokine therapies (Fig. 12.23). However, in order for these inductive modalities to be used effectively *in vivo*, they must be delivered in an appropriately controlled spatiotemporal manner over the timescales necessary to complete stem cell repair and tissue regeneration.

Stem cell-directed gene therapy has demonstrated enormous potential following the cure of children with X-linked severe combined immune deficiency and adenosine deaminase deficiency.^{225,226} However, two of 10 children treated subsequently developed leukemia, significantly tempering enthusiasm for stem cell gene therapy. Another hurdle has been the lack of relevant *in vitro* and animal models to predict efficacy in humans.²²⁷ Lastly, common vector systems currently employed in gene therapy that utilize Moloney murine leukemia virus, human immunodeficiency virus, and lentivirus are far from ideal as concerns regarding adverse inflammatory responses to viral components are always present.

Gene transfer of growth factors such as insulin-like growth factor and FGF has improved wound healing in animal models.^{228,229} Recent studies have demonstrated that lentiviral vectors may be preferred for long-term transfection of skin cells whereas adenoviral or adeno-associated viruses may be better suited for short-term skin therapies.²³⁰ Margolis *et al.* used replication-incompetent adenovirus to express PDGF for chronic venous leg ulcers in a phase I clinical trial.²³¹ Non-viral gene therapies through liposomal gene transfer have also been effectively used for wound regeneration.²³²

Iwaguro *et al.* found that VEGF gene transfer could be used to augment EPC function for vascular regeneration,²³³ and demonstrated improved EPC adhesion, vascular incorporation, and proliferation in a rodent limb ischemia model. EPCs

Fig. 12.23 Induction strategies for gene therapy. Small molecules, plasmids, or liposomes can stimulate stem cell differentiation.

have been transfected to produce anticoagulant proteins in an angioplasty injury model²³⁴ and VEGF-transfected EPCs have been used to fabricate bioengineered vascular grafts.²³⁵ Gene therapy of EPCs has included potential cancer therapy given their avid recruitment to neovascularizing areas.²³⁶

Stem cell-mediated gene therapy has also been proposed for a wide range of neurologic diseases such as Parkinson's disease, Alzheimer's disease, amyotrophic lateral sclerosis, and neuropathic pain.²³⁷ For the treatment of nerve injury, Schwann cells have been transduced to express ciliary neurotrophic factor to augment nerve growth in rats.²³⁸ An adenoviral gene transfer system has also been developed for Schwann cell transfection and peripheral nerve injury.²³⁹ Thus, vector-mediated strategies provide another regenerative tool to control the genetic programming of delivered stem cells with the promise of replacing missing or dysfunctional organs.

iPS cells

Definitions

Pluripotency is the ability of a cell to differentiate into all cell types in the body. Originally thought to be a property unique to the blastocyst or inner cell mass of the early mammalian embryo, this tenet was challenged by a groundbreaking 2007 study published by Yamanaka *et al.* In this paper scientists definitively established a process of reprogramming or "inducing" pluripotency in a mature cell using a few key transcription factors in the cell (Fig. 12.24).²⁴⁰ The resulting cells have been named "induced" pluripotent stem cells as they have stem cell-like properties and can differentiate into all cell types found in the body.

The original conditions for creating iPS cells used a set of four transcription factors: Oct4, Sox2, Klf4, and c-Myc (Fig. 12.25) to revert mature cells into a more primitive stage and induce pluripotency. Since these original studies, scientists have refined the process and are now able to reprogram mature

cells with only two factors. Dr. Yamanaka, who described the original iPS cell, used a stochastic model to illustrate the mechanism behind this type of differentiation. In a stochastic model, most or all differentiated cells have the potential to become iPS cells with the use of four transcription factors. The idea is that a cell represents a "ball rolling down an epigenetic landscape from the totipotent state, going through the pluripotent state and rolling down a lineage committed state". With the development of normal adult cells, pluripotent cells appear briefly and cannot be stopped "on the slope." In contrast, ESCs are blocked by a "bump or roadblock formed by their epigenetic status". Thus, the four Yamanaka factors function to roll cells back to a pluripotent state.²⁴¹

iPS cells have a number of advantages over embryonic stem cells for use in regenerative medicine. Firstly, the use of iPS cells avoids the ethical conflicts associated with ESC derivation as iPS cells are generated from adult tissues. Secondly, since these cells can be harvested noninvasively for autologous re-implantation, they can bypass the immune rejection that limits the use of allogeneic cells. Thirdly, iPS cells can be derived from many different cell types. Early descriptions of iPS derivation used skin fibroblasts,^{242,243} which required only a small skin biopsy followed by 3–4 weeks of *in vitro* expansion. One major disadvantage of skin fibroblasts, however, is that they have a very low reprogramming efficiency (under 0.01%) when using the four Yamanaka factors and even lower without c-Myc. Furthermore, the length of transfection is an additional 3–4 weeks' time before ESC-like iPS cells begin to appear.²⁴⁴ Based on the epigenetic landscape model, fibroblasts are terminally differentiated and thus take a greater amount of time and energy to reprogram.

Keratinocytes from human foreskin biopsies and hair have also been used to generate iPS cells.²⁴⁵ These cells are similarly easy to harvest but also require an extended time for *in vitro* expansion. Compared to fibroblasts, keratinocytes derived from neonatal/juvenile foreskin have an approximate 100-fold increase in reprogramming efficiency. This has not, however, been seen with adult keratinocytes.

Fig. 12.24 Stem cells can be obtained during the different developmental stages of life. With the development of induced pluripotent stem cell (iPS) technology, adult cells can now be reprogrammed to become embryonic "stem cell-like" cells.

Fig. 12.25 By activation of four transcription factors, adult somatic cells can be reprogrammed into induced pluripotent stem cells, which then can differentiate into all the embryonic lineages: ectoderm, mesoderm, and endoderm.

Melanocytes have also been used to generate iPS cells. This is described by Utikal *et al.* in a 2009 paper, which sought to generate iPS cells more effectively by identifying somatic cell populations that could be reprogrammed with greater efficiency.²⁴⁶ Melanocytes inherently express high levels of Sox2 and thus can be reprogrammed with only three factors (Oct4, Klf4, and c-Myc). Original studies using all four Yamanaka factors demonstrated a five-fold higher reprogramming efficiency than seen with fibroblasts. In addition, the melanocytes could be reprogrammed in only 10 days.

Two laboratories have also described iPS cell derivation from cryopreserved umbilical cord blood cells. One laboratory was able to reprogram these cord blood cells successfully using only Oct4 and Sox2.²⁴⁷ A benefit of this technique is that cord blood can be stored for over 5 years and still retain the ability to be reprogrammed.

An even more abundant source of cells for iPS applications is human adipose tissue.²⁴⁸ Our laboratory has isolated adipose cells from lipoaspirates of adult patients and successfully reprogrammed the cells using the four Yamanaka factors. Small-volume liposuction, in a minimally invasive outpatient setting, allows for the harvest of millions of cells. It is estimated that 10 mL of fresh lipoaspirate yields 1 million cells after 48 hours of *in vitro* culture. This allows for immediate reprogramming without prior *in vitro* expansion. Even in slender patients, as little as 15–50 mL of fat can be used to derive iPS cells. Similarly, due to their rapid expansion, hASCs can be reprogrammed with a 20-fold greater efficiency than fibroblasts. Klf4 and c-Myc expression are high in these cells compared to fibroblasts and these cells do not require mouse feeder cells. This ease of harvest and speed of expansion and reprogramming make hASCs an exciting option for scientists exploring translational iPS strategies.²⁴⁸

Despite the excitement generated around iPS cells, methods for their derivation and use need to be further tested and improved. The use of lentiviruses and retroviruses lead to genomic integration of transgenes, which the host cells may not be able to silence completely. Furthermore, both Klf4 and c-Myc, factors commonly used to reprogram cells, are oncogenes. Future directions may involve using small molecules and interfering RNAs, or microRNAs to make iPS cell generation safer. With regard to cell culture, iPS cells still depend on a layer of inactivated MEFs. A Matrigel-coated surface could potentially allow for a feeder-free environment.

More recently, laboratories have found ways to circumvent the use of viruses by generating a non-viral minicircle vector to induce iPS formation.²⁴⁹ Minicircle vectors are supercoiled DNA molecules composed of a eukaryotic expression cassette. Minicircles also offer the advantages of having a higher transfection efficiency and longer ectopic expression due to low activation of exogenous silencing mechanisms. Reprogramming was successfully performed using hASCs from 3 different patients, making it an attractive option if rapid cell expansion and reprogramming are required.²⁴⁹

In 2007, a human sickle-cell anemia mouse model was successfully treated with genetically corrected hematopoietic progenitors generated from iPS cells.²⁵⁰ In spite of promising early successes such as this, however, a number of barriers had to be overcome prior to progression of iPS cell-based therapy to clinical use. For instance, the oncogenic transgene integration and mutagenesis involved in iPS cell reprogramming could induce cancer (Fig. 12.26). Virus-free generated iPS cells offer a potential solution.

Also, significant safety studies are required to determine the minimal number of undifferentiated iPS cells that can become a teratoma as current subcutaneous injection of iPS cells has gone on to generate teratomas. This suggests that iPS cells will likely need to be differentiated *in situ* prior to implantation to allow for appropriate tissue regeneration (Fig. 12.27). Lastly, from a commercialization standpoint, it has yet to be determined if a viable business model for patient-specific iPS treatments is possible given the safety considerations, as well as the challenge of their reprogramming.²⁴⁴

In vitro

Culture and maintenance of iPS cells

IMR90 human fibroblasts or other cell types to be reprogrammed can be maintained with DMEM containing 10% FBS, L-glutamine, 4.5 g/dL glucose, 100 U/mL penicillin, and 100 µg/mL streptomycin. All cells used for reprogramming should be passage two or less. Derived iPS cells can be maintained either on MEF feeder layer or on Matrigel-coated tissue culture dishes (ES qualified; BD Biosciences) with mTESR-1 hES Growth Medium (Stemcell Technology).²⁴⁸

Fig. 12.26 One potential risk of using a multipotent self-renewing cell is the uncontrolled division of these cells leading to tumor formation. However, usually in tissue engineering a paucity of tissue, rather than excess, is the problem.

Lentivirus production and transduction

293FT cells (Invitrogen) are plated at ~80% confluence per 100-mm dish and transfected with 12 μ g each of lentiviral vectors (Oct4, Sox2, Klf4, c-Myc) plus 8 μ g packaging plasmids and 4 μ g VSVG plasmids using Lipofectamine 2000 (Invitrogen) following the manufacturer's instructions. The resulting supernatant should be collected 48 hours after transfection, filtered through a 0.45- μ m pore size cellulose acetate filter (Whatman), and mixed with PEG-it Virus Concentration Solution (System Biosciences) overnight at 4°C. Viruses are precipitated at 1500 g the next day and resuspended with Opti-MEM medium (Invitrogen).

In vitro differentiation

iPS cells cultured on Matrigel are treated with collagenase type IV (Invitrogen) and transferred to ultra-low attachment plates (Corning Life Sciences) in a suspension culture for 8 days with DMEM/F12 (1:1) containing 20% knockout serum (Invitrogen), 4.5 g/dL glucose, L-glutamine, 1% nonessential amino acids, 0.1 mM 2-mercaptoethanol, 50 U/mL penicillin, and 50 μ g/mL streptomycin to allow formation of embryoid bodies (EBs).

The EBs are then seeded in 0.25% gelatin-coated tissue culture dishes for another 3–8 days. Spontaneous differentiation of iPS cells into cells of mesoderm and endoderm lineages can be detected with appropriate markers by immunofluorescence. For osteogenic differentiation, similar osteogenic medium with ascorbic acid, and β -glycerol phosphate have been used along with supplementation of retinoic acid and bone morphogenetic proteins. Furthermore, there remains some dispute as to whether the EB formation step is necessary

Fig. 12.27 When induced pluripotent stem cells (iPS) are placed subcutaneously, there is differentiation into all three embryonic lineages, resulting in the formation of a teratoma. The hope is that these cells can be reprogrammed prior to implantation or *in situ* to repair tissues that cannot be repaired with human adipose-derived stromal cells such as neural tissues.

and leads to more efficient osteogenic differentiation or whether omission of this step is possible. Differentiation into dopaminergic neurons can be performed using a co-culture of hASC iPS cells with PA6 cells.

***In vivo* models and potential clinical correlates**

The use of iPS technology can potentially revolutionize the field of tissue engineering by allowing the creation of any cell type from mature cells harvested via noninvasive methods. We believe that the derivation of iPS cells from hASCs holds several advantages compared to other cell types such as neural stem cells, liver cells, and skin fibroblasts. First, the lipoaspiration procedure for isolating hASCs is relatively simple, fast, and safe. Second, it is easy to obtain a large quantity of hASCs as the starting population for reprogramming after a single lipoaspiration operation. Millions of hASCs can be derived on the same day of lipoaspiration, and the reprogramming can be performed immediately. Up until recently, iPS cells required a layer of mouse fibroblasts to survive in an undifferentiated state, which raised concerns for potential contamination of the cultured human cells by mouse proteins and subsequent rejection by human recipients following transplantation. Feeder-free derivation of iPS cells from hASCs thus represents a more clinically applicable method for derivation of iPS cells and should enable more efficient and rapid generation of patient-specific and disease-specific iPS cells.²⁴⁸

Though the first clinical trial utilizing iPS cells is currently underway in Japan, therapeutic utilization and delivery of iPS cells still requires further refinement. Treatment of a focal deficit such as those present in spinal cord injuries, Parkinson's disease or type I diabetes might involve direct delivery. More systemic diseases such as muscular dystrophies, however, might require multiple intravenous injections for systemic delivery.²⁵¹ The use of animal models can enable scientists to address these and other concerns about safety and efficacy prior to use in humans.

Thus, three main hurdles exist for iPS utilization to become mainstream:

1. Animal proteins are still commonly used during the reprogramming of human cells in the form of a mouse fibroblast feeder layer. A solution would be widespread use of a feeder-free layer or Matrigel without animal components.
2. Currently viruses used for reprogramming can integrate into the genome and cause mutations and possible malignancy. What is needed is a robust and efficient non-viral approach such as the minicircle plasmid for reprogramming.
3. *In vivo*, undifferentiated iPS cells form teratomas. Direct differentiation of iPS cells to the differentiated cells of interest prior to placement *in vivo* may alleviate this concern.

While these hurdles are being addressed, an area of great interest in the realm of iPS cells is that of disease modeling.²⁵² iPS cell technology has provided previously unanticipated possibilities to model rare human diseases *in vitro*.²⁵² Reprogramming somatic cells from affected patients into an embryonic stem cell-like state followed by differentiation into cell types relevant to human disease generates an unlimited source of human tissue carrying the genetic variations that instigated or facilitated disease development. In addition, recently developed gene editing technologies enable the targeted modification of human cells for gene disruptions, genetic repair, or insertion of reporter genes.^{252,253} The ability to modify single base pairs, thereby seamlessly correcting or introducing disease-causing mutations in human pluripotent stem cells, allows the creation of genetically controlled experimental model systems in which the disease-causing genetic variation is the sole experimental variable.²⁵⁴⁻²⁵⁶ This strategy could substantially simplify the analysis of the interaction between these genomic variants and disease phenotypes, thereby revealing new insights into the pathophysiology of monogenic and complex diseases.²⁵²

Wound healing

Chandan K. Sen, Sashwati Roy, and Gayle Gordillo

SYNOPSIS

- There are three general techniques of wound treatment: primary intention, secondary intention, and tertiary intention
- The following overlapping phases drive the overall healing response: hemostasis, inflammation, proliferation, and remodeling
- Successful hemostasis or blood coagulation results in prevention of blood loss by plugging the wound within seconds through vasoconstriction and formation of a hemostatic blood clot consisting of platelets and fibrin. The process is divided into initiation and amplification. Initiation is caused by an extrinsic pathway, whereas amplification is executed by an intrinsic pathway
- The inflammatory response during normal healing is characterized by spatially and temporally changing patterns of specific leukocyte subsets. Dysregulated inflammation complicates wound healing. Complete resolution of an acute inflammatory response is the ideal outcome following an insult
- Infection is a common problem in chronic wounds, frequently resulting in nonhealing wounds and significant patient morbidity and mortality. Microorganisms do not always live as pure cultures of dispersed single cells but instead accumulate at interfaces to form polymicrobial aggregates such as films, mats, flocs, sludge, or biofilms
- In an open wound that has undergone contraction, restoration of an intact epidermal barrier is enabled through wound epithelialization, also known as re-epithelialization. During the proliferative phase of wound healing, the granulation tissue is light red or dark pink in color because of perfusion by new capillary loops. It is soft to the touch, moist, and granular in appearance. The granulation tissue serves as a bed for tissue repair.
- Wound healing endpoint determination should include a combination of visual inspection and measurements of skin barrier function such as transepidermal water loss (TEWL) for accurate determination of closure.
- Wound vascularization may be achieved by angiogenesis or vasculogenesis
- A wound is generally considered chronic if it has not healed in 4 weeks. Chronic wounds can be broadly classified into three major categories: venous and arterial ulcers, diabetic ulcers, and pressure ulcers
- Vascular complications commonly associated with problematic wounds are primarily responsible for wound ischemia. Limitations in the ability of the vasculature to deliver O₂-rich blood to the wound tissue leads to, among other consequences, hypoxia. Three major factors may contribute to wound tissue hypoxia: (1) peripheral vascular diseases garroting O₂ supply; (2) increased O₂ demand of the healing tissue; and (3) generation of reactive oxygen species (ROS) by way of respiratory burst and for redox signaling
- Small RNAs are a new class of regulators of eukaryotic biology. Alongside other small interfering RNAs (siRNAs), microRNAs (miRNAs) execute post-transcriptional gene silencing through mRNA destabilization as well as translational repression. miRNAs are emerging as a key regulator of the overall wound-healing process
- The regenerative potential of injured adult tissue suggests the physiological existence of cells capable of participating in the reparative process. Bone marrow-derived mesenchymal stem cells (BM-MSCs) have been shown to promote the healing of diabetic wounds, implying a profound therapeutic potential for skin defects such as chronic wounds and burns

Introduction

Physical trauma represents one of the most primitive challenges that threatened survival. In other words, injury eliminated the unfit. A Sumerian clay tablet (c. 2150 BC) described early wound care that included washing the wound in beer and hot water, using poultices from substances such as wine dregs and lizard dung, and bandaging the wound. Ancient scriptures depicting the science of life or *Ayurveda* date from the sixth to seventh century BC, and represent the beginning of planned physical injury with the intent to cure.^{1,2} Hippocrates (c. 400 BC) detailed the importance of draining pus from the wound, and Galen (c. 130–200 AD) described the principle of first- and second-intention healing.³ Wound healing advanced slowly over the centuries, with major advances in the 19th century in the importance of controlling infection, hemostasis, and necrotic tissue.⁴ Today, surgical trauma, taken together with injury caused during accidents

Fig. 13.1 (A–C) Phases of cutaneous wound healing: a simplified representation.

and secondary to other clinical conditions, e.g., diabetes, represents a substantial cost to society.⁵ Any solution to wound-healing problems will require a multifaceted comprehensive approach. First and foremost, the wound environment will have to be made receptive to therapies. Second, the appropriate therapeutic regimen needs to be identified and provided while managing systemic limitations that could secondarily limit the healing response. This chapter aims to present an overall outline of the cutaneous wound-healing process.

The wound-healing process

The entire wound-healing process may be viewed as a cascade that is governed by numerous feedback and feed-forward regulatory loops driven by signals from the wound tissue itself, wound microenvironment, as well as interventions under conditions where the wound is subjected to therapy. To understand the several interdigitated biological processes that drive the overall healing response, wound healing is commonly discussed as the following overlapping phases: hemostasis and inflammation, proliferation (granulation,

vascularization, and wound closure; closure may be discussed as wound contraction and epithelialization) and remodeling (continues from weeks to years and encompasses collagen deposition, acquisition of wound tensile strength, and turnover of extracellular matrix (ECM) components). These stages, taken as a whole, are also referred to as the wound-healing cascade (Fig. 13.1).

Hemostasis

For bleeding wounds, the highest priority is to stop bleeding and this is achieved by hemostasis. Hemostasis is thus a protective physiological response to vascular injury that results in exposure of blood components to the sub-endothelial layers of the vessel wall. Through successful hemostasis blood loss is prevented by plugging the wound within seconds through vasoconstriction and formation of a hemostatic blood clot consisting of platelets and fibrin. Hemostasis requires both platelets and the blood coagulation system. The process of blood coagulation may be subdivided into initiation and amplification. Initiation is caused by an extrinsic pathway, whereas amplification is executed by an intrinsic pathway.

Fig. 13.2 The blood clotting cascade. FXII, factor XII, HK, high-molecular-weight kininogen; PF3, platelet factor 3; RBC, red blood cell; TF, tissue factor; TFPI, tissue factor pathway inhibitor; TM, thrombomodulin; WBC, white blood cell.

The intrinsic pathway consists of plasma factor XI (FXI), IX, and VIII (Fig. 13.2). Tissue factor (TF) generates a “thrombin burst”, a process by which thrombin is released instantaneously. Thrombin is a key driver of the overall coagulation cascade.

The extrinsic pathway responsible for the initiation of blood coagulation consists of the transmembrane receptor TF and plasma FVII or VIIa. On the other hand, the intrinsic pathway consists of plasma FXI, FIX, and FVIII. Under physiological conditions, TF is constitutively expressed by adventitial cells surrounding blood vessels and initiates clotting. Examples of such adventitial cells include vascular smooth-muscle cells, pericytes, and adventitial fibroblasts.^{6,7} TF may

also contribute to amplification of blood coagulation through its so-called blood-borne form, which is present as cell-derived microparticles as well as through TF expressed within platelets.⁶⁻⁸

Levels of FVIIa, a key player of the extrinsic pathway, in the circulating blood are higher than any other activated coagulation factor. Following injury to the blood vessel wall, FVII comes into contact with TF expressed on TF-bearing cells (e.g., white blood cells) and forms an activated complex (TF-FVIIa). TF-FVIIa activates FIX and FX, resulting in FIXa and FXa, respectively. FVII is activated by thrombin, FXIa, FXII, and FXa. The activation of FXa by TF-FVIIa is almost immediately inhibited by the TF pathway inhibitor. FXa and

its cofactor FVa form the prothrombinase complex, which activates prothrombin to thrombin. Thrombin is a serine protease that plays a central role in hemostasis after tissue injury by converting soluble plasma fibrinogen into an insoluble fibrin clot and by promoting platelet aggregation. Thrombin activates other components of the coagulation cascade, including FV and FVIII, which in turn activates FIX and cascades to the activation of FX. Thrombin also activates and releases FVIII from being bound to von Willebrand factor. FVIIIa is the cofactor of FIXa, and together they form the “tenase” complex, which activates FX. In this way the cycle continues. The intrinsic pathway begins with formation of the primary complex on collagen by high-molecular-weight kininogen, prekallikrein, and FXII (Hageman factor). Prekallikrein is converted to kallikrein, and FXII becomes FXIIa. FXIIa converts FXI into FXIa. FXIa activates FIX, which together with its cofactor FVIIIa forms the tenase complex. The tenase complex activates FX to FXa (see Fig. 13.2).

The blood clot physically helps plug the wound, minimizing blood loss. It is primarily made up of cross-linked fibrin, cells such as erythrocytes and platelets, as well as other ECM proteins such as fibronectin, vitronectin, and

thrombospondin. Current understanding portrays the clot as a dynamic structural matrix containing functionally active proteins and cells. In addition to containment of blood loss, the clot serves as a first aid against microbial invasion. The clot also serves as a provisional matrix for the homing of blood-borne cells, including inflammatory as well as stem or progenitor cells. The provisional matrix is enriched in cytokines and growth factors which then regulate the function of the homing cells.^{9,10}

The formation of blood clot is initiated by the proteolytic cleavage of fibrinogen by thrombin. As a result, fibrin is produced and forms cross-links with each other. Cross-linked fibrin entraps platelets, and together they adhere to the sub-endothelium through adhesion molecules called integrins. Clot fibrin plays a key role in mounting the inflammatory process as well as in facilitating wound angiogenesis and stromal cell proliferation. Fibrin binds to integrin CD11b/CD18 on infiltrating monocytes and neutrophils. It also binds to fibroblast growth factor-2 (FGF-2) and vascular endothelial growth factor (VEGF) that help the wound tissue vascularize. Fibrin also binds to insulin-like growth factor-I and promotes stromal cell proliferation.^{11,12}

A blood clot represents the seat of wound chemotaxis. Thrombin, released by platelets at the wound site, is an early mediator of clot development.¹³ Thrombin is a serine protease that converts soluble plasma fibrinogen into an insoluble fibrin clot. In addition, it promotes platelet aggregation. Thrombin function may be viewed as an interface between the hemostasis phase of wound healing and the ensuing inflammatory phase as it plays a potent role in mounting wound inflammation. The proinflammatory effects of thrombin include stimulation of vasodilation responsible for plasma extravasation, edema, and an increased expression of endothelial cell adhesion molecules that helps monocytes and other cells extravasate and infiltrate the wound site. Thrombin also induces the release of proinflammatory cytokines like CCL2, interleukin-6 (IL-6), and IL-8 by endothelial cells. These cytokines induce monocyte chemotaxis.¹⁴ Furthermore, thrombin induces the release of inflammatory cytokines by monocytes, including IL-6, interferon- γ , IL-1 β , and tumor necrosis factor- α (TNF- α). These early-phase cytokines are typically proinflammatory, which may govern the differentiation of blood-derived monocytes into M1 wound macrophages.¹⁵ Wound chemotaxis is also driven by the degradation of fibrin and subsequent activation of the complement system. As part of this process, several chemotactic agents and cytokines are released, which in turn launch the inflammatory phase of wound healing through chemotactic recruitment of blood-borne immune cells (Fig. 13.3).¹⁶ Platelets are one of the earliest sources of cytokines which execute immune cell chemotaxis as well as macrophage activation. Once trapped in the fibrin net, platelets release granules that function as a reservoir for biologically active proteins, such as RANTES (regulated on activation, normal T cell expressed, and secreted or CCL5), thrombin, transforming growth factor- β (TGF- β), platelet-derived growth factor (PDGF), and VEGF. CCL5 is one of the most potent monocyte chemoattractants released by platelets after injury. Other cytokines and chemokines that attract monocytes to the wound bed include monocyte chemoattractant protein-1 (MCP-1) (CCL2), MIP-1 α (CCL3), TGF- α , fibronectin, elastin, C5a, C3a, nerve growth factor, and ECM components.^{17,18}

- ① Bacteria and other pathogens enter wound.
- ② Platelets from blood release blood-clotting proteins at wound site.
- ③ Mast cells secrete factors that mediate vasodilation and vascular constriction. Delivery of blood, plasma and cells to injured area.
- ④ Neutrophils and macrophages remove pathogens by phagocytosis.
- ⑤ Macrophages secrete hormones called cytokines that attract immune system cells to the site and activate cells involved in tissue repair.
- ⑥ Inflammatory response continues until the foreign material is eliminated and the wound is repaired.

Fig. 13.3 The wound inflammatory response.

Inflammation

Tissue injury triggers an acute-phase inflammation (Latin, *inflammare*, to set on fire) response that is meant to prepare the wound site for subsequent wound closure (see Fig. 13.3). Inflammation encompasses a series of responses of vascularized tissues of the body to injury. Local chemical mediators that are biosynthesized during acute inflammation give rise to the macroscopic events characterized by Celsus in the first century, namely, *rubor* (redness), *tumor* (swelling), *calor* (heat), and *dolor* (pain). At cellular and molecular levels, inflammation results from the coordination of manifold systems of receptors and sensors that affect transcriptional and post-translational programs necessary for host defense and resolution of infection. During normal healing, the inflammatory response is characterized by spatially and temporally changing patterns of specific leukocyte subsets.

Platelets

Formation of the clot or thrombus is dependent on platelet activation. The platelet-rich blood clot also entraps polymorphonuclear leukocytes (neutrophils). This helps amplify blood coagulation and lays the foundation for the subsequent acute-phase inflammatory response. In a matter of hours after injury, large numbers of neutrophils extravasate by transmigrating across the endothelial cell wall of blood capillaries to the wound site. To enable this, local blood vessels are activated by proinflammatory cytokines such as IL-1 β , TNF- α , and interferon- γ . These cytokines induce the expression of adhesion molecules necessary for adhesion of leukocytes and diapedesis (Fig. 13.4). Adhesion molecules such as integrins as well as P-selectin and E-selectin play a central role in enabling diapedesis of neutrophils (Fig. 13.5). These adhesion molecules bind with integrins expressed on the cell surface of neutrophils, such as CD11a/CD18 (LFA), CD 11b/CD18 (MAC-1), CD11c/CD18 (gp150, 95), and CD11d/CD18. Alongside cytokines, chemokines play a major role in mounting acute-phase inflammation after injury. Chemokines include IL-8, MCP-1, and growth-related oncogene- α . In the case of an infected wound, bacterial products such as lipopolysaccharide and formyl-methionyl peptides can enhance neutrophil recruitment to the wound site (Fig. 13.6).

Neutrophils

Neutrophils traverse postcapillary venules at sites of inflammation, degrade pathogens within phagolysosomes, and undergo apoptosis. Neutrophils serve a wide range of functions, ranging from phagocytosis of infectious agents to cleansing of devitalized tissue. When coated with opsonins (generally complement and/or antibody), microorganisms bind to specific receptors on the surface of the phagocyte and invagination of the cell membrane occurs with the incorporation of the microorganism into an intracellular phagosome. There follows a burst of oxygen consumption, and much, if not all, of the extra oxygen consumed is converted to highly reactive oxygen species. This is called respiratory burst. In addition, the cytoplasmic granules discharge their contents into the phagosome, and death of the ingested microorganism soon follows. Among the antimicrobial systems formed in the

Fig. 13.4 Diapedesis. In healthy permeable capillaries the endothelium lining prevents blood cells from leaving the circulation. In response to injury, blood vessels around the wound site undergo vasodilation, increasing the permeability of capillaries. Such change enables inflammatory cells to extravasate through the capillary wall and migrate to the site of injury. This process includes release of fluid from the vessels to the extracellular space, resulting in the edematous response commonly noted during inflammation. Blood vessels possess a built-in pathway for such diapedesis to occur in response to tissue injury.

phagosome is one consisting of myeloperoxidase (MPO), released into the phagosome during the degranulation process, hydrogen peroxide (H_2O_2), formed by the respiratory burst and a halide, particularly chloride. The initial product of the MPO- H_2O_2 -chloride system is hypochlorous acid, and subsequent formation of chlorine, chloramines, hydroxyl radicals, singlet oxygen, and ozone has been proposed. These same toxic agents can be released to the outside of the cell, where they may attack normal tissue and thus contribute to the pathogenesis of disease.¹⁹ Other products delivered by neutrophils to the wound site include antimicrobials such as cationic peptides and eicosanoids as well as proteases such as elastase, cathepsin G, proteinase 3, and urokinase-type plasminogen activator. The balance of neutrophil-released protease levels and intrinsic inhibitors in the wound environment is important for wound healing progression.²⁰ Chronic non-healing wounds have elevated levels of neutrophil-derived proteases, specifically matrix metalloproteases (MMPs), indicating persistent neutrophil presence. The effects of MMPs are specifically inhibited by the enzymatic group known as tissue inhibitors of matrix metalloproteases (TIMPs) and these are present in abnormally low levels in chronic wounds. The imbalance between MMPs and TIMPs creates a hostile wound

Fig. 13.5 Extravasation of neutrophils in response to tissue injury. Neutrophils move along the capillaries in a rolling motion which is facilitated by the binding and release of L-selectin on the neutrophil surface to sialyl-Lewis x, a carbohydrate ligand expressed on the inner wall of capillaries by endothelial cells. Upon injury and/or infection the release of lipopolysaccharides, tumor necrosis factor- α , and interleukin-1 results in the shedding of L-selectin by the neutrophils which then strongly adhere to the inner wall of the capillary by the binding of integrin on the neutrophils to E-selectins on endothelial cells. After such adhesion, the process of diapedesis begins, allowing the neutrophils to extravasate to the wound site.

Fig. 13.6 Diapedesis and migration of leukocytes to the wound site.

environment as elevated protease levels result in tissue damage and inflammation that self-perpetuates to create a vicious cycle that derails wound healing.

In recent years, another functional component of the neutrophil action response, the neutrophil extracellular traps (NETs), have been a focus of interest. Initially identified as being a beneficial neutrophilic response to pathogens such as bacteria, fungi and viruses,^{21–25} NETs are fibrous chromatin traps that sequester and kill a wide variety of microbes via release of granular components such as elastase, MPO, cathepsin G, lactoferrin and gelatinase.²⁶ Some critical triggers that have been implicated for this process, also called NETosis, include ROS²⁷ and an enzyme (peptidyl arginine deiminase 4 (PAD4)) that post-translationally modifies arginine residues on histones (H3 and H4) resulting in chromatin condensation.^{28–30} An interesting NETosis response to live *Staphylococcus aureus* infection was recently demonstrated *in vitro*, where nuclear material was rapidly released without cytoplasmic contents or lysis of plasma membrane.³¹ These denucleated neutrophils were shown to crawl and phagocytose the bacteria trapped in the created nuclear traps.^{32–34} The presence of anuclear neutrophils that are biologically active have been known since the 1980s³⁵ and possibly reflect a population of neutrophils that have undergone some aspect of NETosis. However, many questions remain to be answered in relation to specific mechanisms of activation of NETs in response to different stimuli such as biofilm infection.

As it relates to the overall inflammatory process elicited in response to injury, neutrophils are major players because they can modify macrophage function and therefore regulate innate immune response during wound healing.³⁶ In the absence of neutrophils, wound site macrophages seem to lack

guidance in conducting the healing process.³⁷ In a healing wound, neutrophil infiltration ceases after a few days of injury. Expended neutrophils are programmed to die and dying neutrophils are recognized by wound site macrophages and phagocytosed. The wound site contains a small portion of macrophages that are resident. Most macrophages at the wound site are recruited from the peripheral circulation. Extravasation of peripheral blood monocytes is enabled by the interaction between endothelial vascular cell adhesion molecule-1 and monocyte very late antigen-4 ($\alpha 4 \beta 1$ integrin). Factors that guide the extravasated monocyte to the wound site include growth factors, chemotactic proteins, proinflammatory cytokines, and chemokines such as macrophage inflammatory protein 1 α , MCP-1, and RANTES. The source of these chemoattractants includes clot-associated platelets, wound edge hyperproliferative keratinocytes, wound tissue fibroblasts and subsets of leukocytes already at the wound site. Once the monocyte leaves the blood vessel to transmute into the wound site through the ECM microenvironment, the process of monocyte differentiation to macrophages has started.

Mediators present in the microenvironment that the monocyte traverses to reach the wound site interact with receptors on the monocyte cell surface, bringing forth major changes in the transcriptomic as well as proteomic make up of the cell. Major examples of such receptors present on the monocyte surface include Toll-like receptors (TLRs; Fig. 13.7), complement receptors, and Fc receptors. At the wound site, macrophages function as antigen-presenting cells and phagocytes scavenging dead cells and debris. In addition, they deliver a wide range of growth factors that are known for their abilities to execute the wound-healing process. Such growth factors include TGF- β , TGF- α , basic FGF (bFGF), VEGF, and PDGF. These growth factors enable wound healing by causing cell proliferation and synthesis of ECM and inducing angiogenesis. Macrophages play a crucial role in enabling wound healing. Macrophage depletion is known to impair wound closure markedly.^{4,38}

Fig. 13.7 Toll-like receptors: responding to infectious agents and the wound microenvironment.

Macrophages

Macrophages represent the predominant cell type in a healing wound 3–5 days following injury. The primary acute function of wound macrophages, which arrive at an injury site hours later than neutrophils, is to operate as voracious phagocytes cleansing the wound of all matrix and cell debris, including fibrin and apoptotic neutrophils. Macrophages also produce a range of cytokines, growth and angiogenic factors that drive fibroblast proliferation and angiogenesis.^{4,39–42} In a classic study, Leibovich and Ross⁴³ demonstrated that antimacrophage serum combined with hydrocortisone diminished the accumulation of macrophages in healing skin wounds of adult guinea pigs. Such depletion resulted in impaired disposal of damaged tissue and provisional matrix, compromised fibroblast count, and delayed healing. Today, macrophages have emerged to be a pivotal driver of efficient skin repair.^{44,45} Monocyte-derived macrophages are highly plastic and can differentiate into proinflammatory (M1) or anti-inflammatory/pro-reparative (M2) phenotypes that can also transdifferentiate into other cell types based on environmental cues and molecular mediators.^{46,47} The macrophage population first taking part in inflammation may change its phenotype to a more anti-inflammatory macrophage and assume the role to resolve inflammation.^{48,49} Macrophages from diabetic wounds display dysfunctional inflammatory responses.⁵⁰ A persistent inflammatory state of diabetic wound macrophages is caused by impairment in the ability of these cells to phagocytose apoptotic cells at the wound site which in turn prevents the switch from M1 to M2 phenotype.⁵⁰ Recently, given the lack of standard, all-encompassing descriptors for macrophages, a collaborative effort was initiated to re-define macrophage nomenclature to encompass the scope of diversity known to

exist in macrophage activation. The proposed nomenclature change would involve inclusion of activation standards based on the source of the activator, be it cytokines such as IL-4, IL-10 or bacterial lipopolysaccharide (LPS) (e.g. M(IL-4), M(IL-10), M(LPS), etc., where M refers to macrophage) and where relevant, a combination of macrophage-specific surface markers or lack thereof to describe activation outcomes.⁵¹

Mast cells

Mast cells are best known for their central role in mediating allergic responses. Beyond that function, it is now known that mast cells are physiologically significant in recognizing pathogens and in regulating immune response.⁵² Mast cells may instantly release several proinflammatory mediators from intracellular stores. In addition, they are localized in the host–environment interface. These properties make mast cells key players in fine-tuning immune responses during infection. Recent studies using mast cell activators as effective vaccine adjuvants show the potential of harnessing these cells to confer protective immunity against microbial pathogens.⁵³ Mast cell activation helps initiate the inflammatory phase of wound healing. In response to injury, mast cells at the wound site degranulate within a matter of hours and therefore become histologically silent at the wound tissue. After about 48 hours of injury, mast cells are again seen in the wound tissue and their number increases as healing progresses.⁵⁴ On one hand, impaired wound healing has been reported in mast cell-deficient mice.⁵⁵ On the other hand, mast cells have been implicated in skin wound fibrosis.⁵⁶ With the aid of a wide array of newly formed or preformed mediators released by degranulation, the activated mast cell controls the key events of the healing phases: triggering and modulation of the inflammatory stage, proliferation of connective cellular elements, and final remodeling of the newly formed connective tissue matrix. The importance of the mast cell in regulating healing processes is also demonstrated by the fact that a surplus or deficit of degranulated biological mediators causes impaired repair, with the formation of exuberant granulation tissue (e.g., keloids and hypertrophic scars), delayed closure (dehiscence), and chronicity of the inflammatory stage.⁵⁷

Resolution of inflammation

Inflammatory responses elicited by injury are only helpful to the healing process if they are timely and transient. Dysregulated inflammation complicates wound healing and prevents progression of the wound healing cascade beyond the inflammatory phase.⁵⁸ For resolution of inflammation to ensue, further leukocyte recruitment must be halted and accompanied by removal of leukocytes from inflammatory sites. At the wound site successful phagocytosis of dead neutrophils by macrophages is a key factor. Impairment in macrophage function, as is commonly seen with diabetes, derails the resolution of inflammation.⁵⁸ Lipid mediators, such as the lipoxins, resolvins, protectins, and newly identified maresins, have emerged as a novel genus of potent and stereoselective players that counterregulate excessive acute inflammation and stimulate molecular and cellular events that define resolution.⁵⁹ Successful resolution paves the path for the healing process to progress towards successful wound closure. Prolonged inflammation may not only compromise wound closure but may also worsen scar outcomes.⁶⁰ The inappropriate and

sustained levels of inflammation observed in various chronic wound states could be induced by microbial biofilms and certainly contribute to derailing the wound healing process.⁶¹ Bacteria come armed with various virulence factors that stimulate a proinflammatory response in the wound microenvironment that interfere with the normal pattern of host responses. Details on the role of infection, particularly bacterial biofilm infection in wound healing, are covered in the section on [chronic wounds](#).

Proliferative phase

The proliferative phase starts around 2 days after injury and normally lasts up to 3 weeks in a healing cutaneous wound. This phase overlaps with the inflammatory phase and supports re-epithelialization, the formation of new blood vessels, and the influx of fibroblasts and laying down of the ECM. By the time this phase begins, the degradation of the fibrin clot by the macrophages has begun and invading endothelial cells and fibroblasts rapidly fill that space. Migrating fibroblasts produce the cytokines that induce keratinocytes to migrate and proliferate.⁶² Activated macrophages produce several cytokines, such as PDGF and TNF- α , which also induce fibroblasts to produce keratinocyte growth factor which in turn induces wound re-epithelialization.^{63,64}

Granulation tissue

The fibrin clot formed during hemostasis participates in the early inflammatory phase and is replaced by a perfused, fibrous connective tissue that grows from the base of a wound and is able to fill wounds of almost any size. During the proliferative phase of wound healing, this granulation tissue is light red or dark pink in color because of perfusion by new capillary loops. It is soft to the touch, moist, and granular in appearance. The granulation tissue serves as a bed for tissue repair. The ECM of granulation tissue is created and modified by fibroblasts. Initially, it consists of a network of type III collagen, a weaker form of the structural protein that can be produced rapidly. This is later replaced by the stronger, long-stranded type I collagen, as evidenced in scar tissue. Formation and contraction of the granulation tissue represent integral aspects of the healing wound. In ischemic wounds, production and contraction of the granulation tissue is impaired because of decreased ATP production, impaired collagen synthesis and failure to convert the fibroblast phenotype into a myofibroblast to promote wound contraction.⁶⁵

Vascularization

Wounds complicated by underlying ischemia largely rely on wound vascularization for their closure. Wound vascularization may be achieved by angiogenesis or vasculogenesis. Angiogenesis represents sprouting of capillaries from existing blood vessels in the wound edge tissue. Vasculogenesis relies on the formation of new blood vessels by mobilization of bone marrow-derived endothelial stem cells.

Wound vascularization is regulated by all phases in wound healing – hemostasis, inflammation, tissue formation, as well as tissue remodeling. The hemostatic plug provides a bed to attract blood-borne cells to the wound site. Once cells entangle in this plug, the ECM environment modifies cell function

towards successful healing. Platelets in the clot serve as a source of growth factors and cytokines, which recruit several cell types, including endothelial cells, to the wound site. During the inflammatory phase, leukocytes at the wound site serve as a major source of pro-angiogenic factors such as VEGF-A and IL-8 that lay the early foundation for successful wound tissue vascularization. As neutrophils are expended and undergo cell death, the number of macrophages at the wound site substantially increases. Macrophage-derived TGF- β , TGF- α , bFGF, PDGF, and VEGF play a key role in driving skin wound angiogenesis. Growing evidence demonstrates that no single angiogenic factor is singularly effective in significantly influencing wound outcomes. Wound vascularization is a sophisticated process requiring dynamic, temporally and spatially regulated interaction between cells, angiogenic factors, and the ECM.

Key processes in tissue vascularization are depicted in [Fig. 13.8](#). Angiogenic cues are elicited by microenvironmental signals such as hypoxia and are amplified by angiogenic factors such as VEGF expressed by and released from cells at the wound site. VEGF was originally identified as an endothelial cell-specific growth factor stimulating angiogenesis and vascular permeability. Some family members, VEGF C and D, are specifically involved in lymphangiogenesis. Ligation of these angiogenic factors with their corresponding receptors elicits a multitude of cell-signaling processes that activate microvascular endothelial cells. For example, VEGFs and their endothelial tyrosine kinase receptors are central regulators of tissue vascularization. VEGF signaling through VEGFR-2 is the major angiogenic pathway. VEGFR-3 has also been shown to be important for angiogenesis, acting together with VEGF/VEGFR-2 and Dll4/Notch signaling to control angiogenic sprouting.⁶⁶ The biological significance of other angiogenic factors such as EGF and bFGF is mediated by their corresponding receptors, which also belong to the family of tyrosine kinase receptors EGFR, FGFR-1, FGFR-2, FGFR-3, and FGFR-4.

Other tyrosine kinase receptors of outstanding significance in this regard are Tie-1 and Tie-2. Along with the VEGF receptor, these are the only known endothelial cell-specific receptor tyrosine kinases. Tie-2 is induced on the endothelium of neovessels in skin wounds and downregulated as newly formed vessels regress. As an indicator of Tie-2 activation, Tie-2 phosphorylation is detected in skin wounds at all stages of the healing process.⁶⁷ Activated microvascular endothelial cells respond by proliferating, which is followed by directional migration of these cells. Migration is a complex process in which cells move in a given direction either in response to changes in the extracellular environment or as a consequence of an intrinsic propensity for directional movement. ECM remodeling by proteases promotes cell migration, a critical event in the formation of new vessels. Temporal and spatial regulation of ECM remodeling events allows for local changes in net matrix deposition or degradation, which in turn contributes to control of cell growth, migration, and differentiation during different stages of angiogenesis. Matrix-bound growth factors released by proteases and/or by angiogenic factors promote angiogenesis by enhancing endothelial migration and growth. Matrix molecules promote endothelial cell growth and morphogenesis, and/or stabilize nascent blood vessels. Hence, ECM molecules and ECM remodeling events play key roles in regulating angiogenesis.⁶⁸

Fig. 13.8 Neoangiogenesis: the formation of new blood vessels. VEGF, vascular endothelial growth factor; ECM, extracellular matrix.

The formation of the capillary-like tubes is specific to endothelial cells and integral to the process of angiogenesis. The basement membrane represents a biologically functional highly specialized ECM on which the basal non-luminal surface of endothelial cells rests. This matrix forms a continuous sleeve around the endothelial cells, and maintains the tube-like structures of the blood vessels. More than 20 years ago Kubota *et al.* observed that endothelial cells plated on a reconstituted basement membrane matrix, rapidly attached, aligned, and formed capillary-like tubules. The cells did not proliferate. The vessels that are thus formed contain a lumen and tight cell-cell contacts. The cells are polarized with the nuclei basally located towards the basement membrane matrix. Furthermore, the capillary-like structures take up acetylated low-density lipoprotein, which is a marker of differentiation for these cells.⁶⁹ Angiogenesis not only depends on endothelial cell invasion and proliferation, but also requires pericyte coverage of vascular sprouts for vessel stabilization. These processes are coordinated by VEGF and PDGF through their cognate receptors on endothelial cells and vascular smooth-muscle cells, respectively.⁷⁰ Structural support to blood vessels is provided to pericytes and vascular smooth-muscle cells. Normal pericytes are embedded within the basement membrane of capillaries, either as solitary cells or a single-cell layer, where they coordinate intercellular signaling with endothelial cells and other components of the blood vessel wall to prevent leakage. In contrast, vascular smooth-muscle cells form single or multiple layers around arteries and veins to mediate vascular tone and contraction. Pericyte coverage is required for the stabilization of immature endothelial tubes.⁷¹ Pericytes have functions beyond angiogenesis that are relevant to wound healing. Skin pericytes are very plastic and may act as mesenchymal stem cells (MSCs), exhibiting the capacity to differentiate into bone, fat, and cartilage lineages. Thus, pericytes represent a potent stem cell population in the skin that is capable of modifying the ECM

microenvironment and promoting epidermal tissue renewal from non-stem cells.⁷²

Wound closure

Wound contraction and re-epithelialization contribute to closure of wounds that heal by secondary intention. Wound contraction represents an early response to injury that is aimed at juxtaposing the edges of an open wound.⁷³ This early phase of wound closure appears to be mediated by a contractile “purse-string” force produced by a circumferentially arranged band of fusiform-shaped epidermal cells situated in the wound margin.⁷⁴ Fibroblasts at the wound edge tissue are recognized to play a key role in enabling wound contraction.⁷⁵ During the inflammatory phase of wound healing, fibroblasts acquire smooth-muscle cell characteristics and differentiate into contractile myofibroblasts. The first phenotypic transition of wound edge fibroblasts into so-called protomyofibroblasts is characterized by neoformation of contractile β -cytoplasmic actin stress fibers and occurs in response to profibrotic cytokines and to altered properties of the ECM. In the presence of TGF- β 1 in a mechanically restrained environment, these cells express α -smooth-muscle actin *de novo*, which significantly increases their contractile activity and is a hallmark of the differentiated myofibroblast.⁷⁶ Wound contraction may significantly contribute to wound closure, although this contribution is much larger in loose-skinned rodents than in humans.

In an open wound that has undergone contraction, restoration of an intact epidermal barrier is enabled through wound epithelialization, also known as re-epithelialization.^{77,78} A wound that is not epithelialized is not considered “healed”, no matter how perfectly restored the underlying dermal structures may be. Thus, wound epithelialization is a critical and defining feature of wound repair. Re-epithelialization of

the wound can be conceptually viewed as the result of three overlapping keratinocyte functions: migration, proliferation, and differentiation. The sequence of events by which keratinocytes accomplish the task of re-epithelialization is generally believed to begin with dissolution of cell–cell and cell–substratum contacts. This is followed by the polarization and initiation of directional migration in basal and a subset of suprabasilar keratinocytes over the provisional wound matrix. A subset of keratinocytes immediately adjacent to, but not within, the wound bed then undergoes mitosis. Finally, there is multi-layering of the newly formed epidermis and induction of differentiation-specific gene products to restore the functionality of the epidermis. The most limiting factor in wound re-epithelialization is migration, since defects in this function, but not in proliferation or differentiation, are associated with the clinical phenotype of chronic non-healing wounds.⁷⁹ The process of epithelialization continues until the barrier is re-established and the wound is covered. The process of re-epithelialization is accelerated by a moist environment^{80,81} and is facilitated by the enzyme matrix metalloproteinase 1, a collagenase which lessens the affinity of the collagen–integrin contacts.⁸²

MicroRNAs

Wound healing is largely dependent on injury-inducible protein-coding genes as they serve as drivers of an inherent tissue repair program that seeks to restore the injured tissue both structurally as well as functionally. There are two key steps that separate a protein-coding gene from its corresponding protein. First, the DNA hosting the gene must transcribe to mRNA and second, the mRNA must be translated to protein. Work emerging during recent years demonstrates that both of these critical steps are subject to robust and redundant regulation by microRNAs (miRNAs: 19–22 nucleotides long), which are noncoding RNAs found in all eukaryotic cells. Work during the past decade recognizes small RNAs as a new class of regulators of eukaryotic biology that could be classified as epigenetic regulators of gene expression.⁸³ Alongside other small interfering RNAs (siRNAs), miRNAs execute post-transcriptional gene silencing through mRNA destabilization as well as translational repression. In simple terms, whether a gene would code a protein or not is decided by miRNAs for which the gene is a target. miRNAs form base pairs with specific sequences in protein-coding mRNAs. Near-perfect pairing induces cleavage of the target mRNA, whereas partial pairing results in translational repression and mRNA decay through deadenylation pathways.⁸⁴ According to the miRbase database, the human genome encodes 1881 miRNAs. This count is rapidly growing. These miRNAs may regulate more than a third of all protein-coding genes and virtually all biological processes. Mammalian cells express cell type-specific miRNAs which silence unique subsets of target genes within the cell. While miRNAs are mostly known for being functional in the cytoplasm, nuclear miRNAs may also participate in gene regulation. Initially considered an oddity, miRNA-dependent control of gene expression is now accepted as being integral to the normal function of cells and organisms.⁸⁵ miRNAs are emerging as key regulators of the overall wound-healing process.^{86–88} miRNA dependent regulation of processes as it relates to wound healing are discussed

in subsequent sections in this chapter. The regulation of a variety of functionally related genes by modulating a single miRNA holds promise for miRNA-based therapeutics. As the knowledge of specific roles of miRNAs continues to grow, the emergence of miR-based therapies that specifically upregulate beneficial miRs and/or downregulate potentially harmful miRs will emerge as useful tools in the clinic. miRNA dependent regulation of specific phases in wound healing are mentioned in the section on [chronic wounds](#).

Acute wounds

Any violation of live tissue integrity may be regarded as a wound. Skin is the largest organ of the human body, covering about 3000 square inches (7620 cm²) in an average adult. The most important role of the skin for terrestrial animals is to protect the water-rich internal organs from the dry external environment. As a primary line of defense against external threats, maintenance of integrity of the skin is a key prerequisite for healthy survival. Thus, healthy skin can regenerate and repair itself under most common conditions. Skin wounds may be open when manifested as a tear, cut, or puncture. Blunt force trauma may cause closed wounds or contusion where the skin appears to be intact but suffers from damage caused to underlying tissues.

Open wounds may be generally categorized as:

- Lacerations – ragged tears and cuts; masses of torn tissue underneath; caused by dull knife, bomb fragments and machinery and may include crushing of tissues; frequently contaminated ([Fig. 13.9](#))
- Puncture – e.g., sharp penetrations caused by nails, needles, wire, or bullets (see [Fig. 13.9](#)). These are of great concern in patients with diabetes, as many of these patients have polyneuropathy and have insensate feet, leading to occult injury. Many times these patients will step on thumb tacks, safety pins, or other sharp household objects and not even know it: this, coupled with compromised vascular status, leads to chronic wound infection
- Abrasions – the superficial layer of the skin is removed; skinned knee or elbows and rope burns are examples; an abrasion lends itself to infection

Fig. 13.9 Laceration and puncture wounds.

- Avulsions – sections of skin torn off either in part (attached to body) or totally (detached from body); heavy bleeding is common
- Amputations – traumatic amputation results in nonsurgical removal of limb from the body and accompanies heavy bleeding.

There are three general techniques of wound treatment:

1. Primary intention, in which all tissues, including the skin, are closed with suture material after completion of the operation
2. Secondary intention, in which the wound is left open and closes naturally
3. Tertiary intention, in which the wound is left open for a number of days and then closed if it is found to be clean.

Factors that promote healing

Nutrition

The importance of adequate nutrition to supplement and sustain the energy-intensive process of wound healing has been established for many years.^{89–92} The need for nutrients such as carbohydrates, protein, fat, amino acids, vitamins and mineral supplements is underscored by the observations that in malnutrition conditions or lack of sufficient nutritional supplementation, processes critical to wound healing are impeded. These include delayed neovascularization, decreased collagen synthesis leading to impaired mechanical strength of the skin and prolonged inflammation leading to dysfunctional immune responses.^{89,93–96} Since the identification of malnutrition as a reversible risk factor for pressure ulcer development,⁹⁷ recommendations have been made for the inclusion of validated nutrition screening and assessment tools to determine nutritional status. Serum pre-albumin (transerythrin) has a shorter half-life than albumin and may serve as a more sensitive indicator of changes in protein-energy status. It is recommended as a good screening tool for malnutrition if used as two measurements taken 3–5 days apart along with CRP levels.⁹⁸

Fats (particularly short chain fatty acids (SCFAs) such as butyrates, acetate and propionate) and carbohydrates (such as glucose) provide the primary energy source for collagen synthesis and deposition and angiogenesis. The American Society for Parenteral and Enteral Nutrition and the Wound Healing Society guidelines for optimal wound healing recommends 30–35 kcal.kg⁻¹.d⁻¹ for normal, healthy adults and 35–40 kcal.kg⁻¹.d⁻¹ for adults suffering from malnutrition.

Fibroblast proliferation, collagen deposition, formation of vascular supply and immune responses are dependent on the availability of proteins, which are the building blocks of wound repair. The recommended range of protein intake for wound healing is 0.8–1 g.kg⁻¹.d⁻¹ in normal adults and higher (up to 2 g.kg⁻¹.d⁻¹) for chronic wound patients. The amino acids arginine and glutamine have been studied for their roles in wound healing, particularly related to collagen deposition, angiogenesis and immune function.^{89,93,99–101} However, it still remains unclear how essential these and other amino acids are in specific aspects of wound healing.

Vitamins A, C and E have potent antioxidant and anti-inflammatory effects that are implicated in promoting proper tissue repair. The stimulation of immune responses,

re-epithelialization, and collagen deposition have all been linked to the presence of adequate levels of each of these vitamins independently.⁹⁵

Micronutrients such as magnesium, copper, zinc and iron serve as co-factors particularly for enzymes that support the wound healing process.^{89,93,99}

Therapeutic oxygen

Oxygen directly impacts wound healing by targeting numerous molecular targets and cell types. Increased fibroblast proliferation and migration, increased collagen synthesis and the resulting increase in the tensile strength of collagen fibers, stimulation of angiogenesis, promotion of immune functions such as macrophage chemotaxis, leukocyte antibacterial and physiological wound debridement functions are all attributed to the essential role of oxygen in healing wounds.^{102,103} Therefore, the use of direct oxygen supplementation to improve wound healing is a natural extension of these observations. The therapeutic oxygen modalities that are used to treat wounds are described in more detail in later sections in this chapter.

Chronic wounds

Factors that drive wound chronicity

Infection and biofilm

Infection is a common problem in chronic wounds, frequently resulting in non-healing and significant patient morbidity and mortality.¹⁰⁴ Wound infection and the subsequent release of proinflammatory modulators result in pain and delayed healing. The pain, in turn, compromises the immune response to infection.¹⁰⁵ All wounds become contaminated by bacteria from the surrounding skin, the local environment, and autologous patient sources. The local environment is particularly relevant for hospitalized patients. Colonization is defined as the presence of proliferating bacteria without a noticeable host response. Colonization of the wound may enhance or impede wound healing, depending upon the bacterial load. Bacterial loads in excess of 10⁵ organisms per gram of tissue are a threat to wound healing, although this threshold may be altered by the status of the host immune system and the number and types of bacterial species present. The concept of critical colonization, characterized by increased bacterial burden or covert infection, is controversial and not universally accepted. Substantial colonization may not cause obvious signs of inflammation, but may affect wound healing with failure to heal or slowing of progression. Signs of critical colonization are atrophy or deterioration of granulation tissue, discoloration of granulation tissue to deep red or gray, increased wound friability, and increased drainage. The transition to infection occurs when bacterial proliferation overcomes the host's immune response and host injury occurs. Several factors determine transition from colonization to infection: the bioburden itself, the virulence of the organisms, the synergistic action of different bacterial species, and the ability of the host to mount an immune response.¹⁰⁴

During the past decade, there has been rapid progress in the understanding of innate immune recognition of microbial

Fig. 13.10 Scanning electron microscopy (SEM) images of planktonic and biofilm mode of the Gram-negative pathogen *Pseudomonas aeruginosa*.

components and its critical role in host defense against infection. The early concept of innate immunity was that it non-specifically recognized microbes; however, the discovery of TLRs (Fig. 13.7) in the mid-1990s showed that pathogen recognition by the innate immune system is instead actually specific, relying on germline-encoded pattern recognition receptors (PRRs) that have evolved to detect components of foreign pathogens, referred to as pathogen-associated molecular patterns (PAMPs).¹⁰⁶ TLRs regulate innate and adaptive immune responses and are important modulators of inflammation during wound-healing responses. The finding that there is activation of TLR signaling during tissue damage in several disease situations in the absence of infection suggests that endogenous molecules serve as TLR agonists, although it is unclear whether this response is biologically important for maintenance of homeostasis, such as tissue repair, or whether this recognition is simply accidental. It is noteworthy that microbial infection triggers the production of modified endogenous molecules (such as high-mobility group protein B1, oxidized phospholipids, β -defensin 2, and nucleic acids) that are recognized by TLRs or other cytosolic PRRs. This may suggest that these endogenous molecules, along with PAMPs, act as adjuvants to activate innate immune programs via TLRs and/or other PRRs, and have key roles in facilitating adaptive immunity against infecting microbes.

Chronic wounds have a complex colonizing flora that changes over time. *Staphylococcus aureus* and coagulase-negative staphylococci are the most commonly isolated organisms. Chronic wounds are colonized by multiple bacterial species and many persist in the wound once they are established. In chronic venous leg ulcers the most common bacteria noted, in order of abundance, were *S. aureus*, *Enterococcus faecalis*, *Pseudomonas aeruginosa*, coagulase-negative staphylococci, *Proteus* spp., and anaerobic bacteria. Resident (colonizing) bacterial species are commonly present in ulcers. The longer an ulcer remains unhealed, the more likely it will acquire multiple aerobic organisms and a significant anaerobic population. Chronic wounds are commonly complicated by localized ischemia because of disruption of the vessels at the site of tissue injury. Thus, they tend to have a low tissue oxygen level. This facilitates the growth of anaerobes in ischemic wounds. Adequate delivery of oxygen to the wound tissue is vital for optimal healing and resistance to infection.¹⁰⁷ Hospitalization, surgical procedures, and prolonged or

broad-spectrum antibiotic therapy may predispose patients to colonization or infection, or both, with resistant organisms, including *S. aureus* (methicillin-resistant *S. aureus* – MRSA) or vancomycin-resistant enterococci (VRE).¹⁰⁸ Inflammatory responses to microbial invasion may be diminished in persons with diabetes or other immunosuppressive conditions.¹⁰⁸

Microorganisms do not always live as pure cultures of dispersed single/planktonic cells but instead accumulate at interfaces to form polymicrobial aggregates such as films, mats, flocs, sludge, or biofilms (Fig. 13.10). The biofilm state of microorganisms may lead to an increase in virulence and resistance to antibiotic therapy and evasion of host immune response. In most biofilms, the microorganisms account for less than 10% of the dry mass, whereas the matrix can account for over 90%. The matrix is the extracellular material, mostly produced by the organisms themselves, in which the biofilm cells are embedded. It consists of a conglomeration of different types of biopolymers – known as extracellular polymeric substances (EPS) – that aid in adhesion to surfaces, form the scaffold for the developing biofilm and also provide a physical barrier that is relatively impenetrable to antimicrobial substances and immune responses. The formation of a biofilm allows a lifestyle that is entirely different from the planktonic state. Although the precise and molecular interactions of the various secreted biofilm matrix polymers have not been defined, several functions of EPS have been determined, demonstrating a wide range of advantages for bacteria in a biofilm state. The architecture of biofilms as determined by *in vitro* studies is influenced by many factors, including hydrodynamic conditions, concentration of nutrients, bacterial motility, and intercellular communication, as well as exopolysaccharides and proteins.¹⁰⁹ These studies involving the use of abiotic (e.g. Calgary biofilm device, modified Robbins device, Bioflux systems, etc.) or biotic surfaces (e.g. reconstituted human epithelia (RHE), Lubbock model, tissue-engineered equivalents such as Graftskin) have helped to understand numerous mechanistic aspects of biofilm growth such as intercellular communication involving quorum sensing, antimicrobial tolerance and also testing the efficacy of antibiofilm therapeutics. However, the clinical relevance of these studies is limited because of the inability to address the iterative host response to the presence of biofilm that defines the establishment of chronic infection. *In vivo* studies on biofilms have included a range of model organisms from the common

fruit fly (*Drosophila melanogaster*) to vertebrates such as rats, mice, rabbits and pigs, each with its own advantages and disadvantages.^{110,111} The high homology between porcine and human skin, the similarities in the immune responses compared to rodent models and the observation that in relation to wound therapies, porcine studies were in agreement with humans 78% of the time compared to 53% and 57% with rodents and *in vitro*, respectively, make the porcine model translationally relevant as recommended by the Wound Healing Society.¹¹² Recently, a chronic wound biofilm model was developed with the goal of understanding long term host-biofilm interactions that drive wound chronicity. This model was used to demonstrate that persistent biofilm infection compromised wound healing by interfering with tight junction proteins that are critical for maintenance of skin barrier function.¹¹³

Wounds provide an ideal environment for biofilm development. The extracellular matrix components such as collagen, fibronectin and laminin could serve as ligands for attachment of bacteria to initiate colonization. Wound beds are moist and nutritious and provide the conditions that would allow micro colonies of bacteria to develop surrounded by the protective barrier of the matrix provided the initial colonization is successful. In fact, it is estimated that 60% of chronic human wounds are infected with biofilm bacteria emphasizing an important role for the sessile, aggregated mode of bacterial growth as factors in chronicity.¹¹⁴ Compared to bacteria in the unattached free-living planktonic form, bacteria that reside within mature biofilms are highly resistant to traditional antibiotic therapies. Bacteria in biofilms grow more slowly, and slower growth may lead to decreased uptake of the drug and other physiologic changes that could impair drug effectiveness.¹⁰⁹

There are several features of biofilm infection in wounds that represent significant clinical and diagnostic challenges. First, bacteria in a biofilm state cannot be cultured reliably using standard culture methods and the gram stain frequently will not show inflammatory cells, so even when bacteria are seen on the gram stain they are diagnosed as colonizing organisms not pathogens. In a case series of sternal wound infections only two out of six patients with staphylococcal biofilm infection had positive cultures, but staphylococcal biofilm was detected on sternal wires in all six patients using scanning electron microscopy.¹¹⁵ Second, debridement alone does not effectively eradicate biofilm infection. It can drive biofilm-producing bacteria deeper into the surrounding tissue with recurrence of biofilm infection within 7 days.¹¹³ Additionally, aberrant host immune responses to biofilm infection are implicated in the persistence of infection and wound chronicity.^{61,116–124} Biofilms of *Pseudomonas* and *Staphylococcus* spp. trigger the host response by recruitment of polymorphonuclear leukocytes to the sites of the biofilm. However, after recruitment, these host cells are frustrated in their expected function of clearing the infection because of biofilm-specific arsenal such as alginate and rhamnolipids (*Pseudomonas* specific) or polysaccharide intercellular adhesins (PIA, *Staphylococcus* specific) that hold the host response at bay.¹²³ By definition bacteria in a biofilm state are adherent to a surface, e.g. a catheter, an implant, soft tissue or bone in a wound¹²⁴, so they will not result in bacteremia and systemic illness. Since scanning electron microscopy is not clinically available, and current culture methods are unreliable, the diagnosis of

biofilm infection is based primarily upon clinical findings. Biofilm infection is the clinical paradigm that can be consistently applied to all chronic wounds and likely represents a unifying pathologic feature. Therefore, there is a strong need to understand the clinical biofilm.

Determining clinical endpoints

The FDA defines **complete wound closure** of chronic non-healing wounds as “skin closure (as assessed visually) without drainage or dressing requirements identified at two consecutive study visits that are 2 weeks apart” and requires therapeutic trials for chronic wounds to be designed such that the enrolled patients will be evaluated for at least 3 months following complete closure.¹²⁵ Here, the expectation is that successful intervention should keep the wound closed for at least 90 days. The determination of wound closure is based primarily on visual assessments. However, such visually closed wounds are sometimes prone to post-closure complications such as recurrence. Indeed high recurrence rates have been reported for chronic wounds (40–79% for pressure ulcers (PUs), 24–57% for venous leg ulcers (VLUs) and upward of 60% for diabetic foot ulcers (DFUs)).^{126–131} Recent evidence indicates that biofilm-infected wounds appear visually closed, but remain functionally open (high transepidermal water loss (TEWL_{hi})) because of elevated levels of biofilm-induced microRNAs (miR-146a and miR-106b) and dysregulated tight junction proteins (ZO-1 and ZO-2) (Fig. 13.11). This challenges the current assessment of visual wound closure and emphasizes the need for additional measurements such as TEWL in the objective and comprehensive monitoring of wound healing.¹¹³

miR regulation of skin barrier function

Evidence from Dicer ablation and microRNA overexpression studies in the intestinal epithelium have supported roles for miRNA regulation of epithelial barrier function.¹³² In the cutaneous epithelium, recent studies have identified roles for miRs in the regulation of skin barrier function. miR-dependent silencing of cellular tight junction proteins resulting in compromised epithelial barriers was recently identified and miR-146a was validated to directly target ZO-1 and ZO-2,¹¹³ key tight junction proteins that are essential for the establishment of proper junctional connections between skin cells^{133–135} that contribute to proper skin barrier function. miR-146a along with miR-106b were also identified as being biofilm inducible. More recently, keratinocyte-specific Dicer ablation studies in a mouse model also supported roles for the miRNA regulatory pathway in proper establishment of barrier function via the p21^{waf1/Cip1} pathway following wounding.¹³⁶

Ischemia and tissue oxygenation

Vascular complications commonly associated with problematic wounds are primarily responsible for wound ischemia. Limitations in the ability of the vasculature to deliver O₂-rich blood to the wound tissue lead to, among other consequences, hypoxia. Hypoxia is a reduction in oxygen delivery below tissue demand, whereas ischemia is a lack of perfusion, characterized not only by hypoxia but also by insufficient nutrient supply.¹⁰³ Hypoxia, by definition, is a relative term. It is

Fig. 13.11 Induction of biofilm-inducible miRs in infected wounds followed by silencing of tight junction proteins ZO-1 and ZO-2, results in compromised skin barrier function indicated by high transepidermal water loss (TEWL) measurements (TEWL_{hi}). Such wounds may appear to be visually closed but are functionally open (leaky/failed skin).

defined by a lower tissue partial pressure of oxygen (pO_2) compared to the pO_2 to which the specific tissue element in question is adjusted under healthy conditions *in vivo*. Depending on the magnitude, cells confronting hypoxic challenge either induce an adaptive response that includes increasing the rates of glycolysis, conservation of energy or progression to cell death. Generally, acute, mild to moderate hypoxia supports adaptation and survival. In contrast, chronic, extreme hypoxia leads to tissue loss.

While tumor tissue is metabolically designed to thrive under conditions of hypoxia, hypoxia of the wound primarily caused by vascular limitations is intensified by coincident conditions (e.g., infection, pain, anxiety and hyperthermia) and leads to poor healing outcomes. Oxygen and its reactive derivatives (Fig. 13.12) are required for oxidative metabolism-derived energy synthesis, protein synthesis, and the maturation (hydroxylation) of extracellular matrices such as collagen. Molecular oxygen is also required for nitric oxide (NO) synthesis which in turn plays a key role in the regulation of vascular tone as well as in angiogenesis. In a wound setting, large amounts of molecular oxygen are partially reduced to form reactive oxygen species (ROS). ROS include oxygen free radicals such as superoxide anion as well as its non-radical derivative, hydrogen peroxide (H_2O_2). Superoxide anion radical is the one-electron reduction product of oxygen. NADPH oxidases represent one major source of superoxide anion radicals at the wound site. NADPH oxidases in phagocytic cells help fight infection. Superoxide anion also drives endothelial cell signaling such as that required during

Fig. 13.12 Molecular oxygen and its derivatives in wound healing. ATP, adenosine triphosphate; NO, nitric oxide.

angiogenesis. In biological tissues, superoxide anion radical rapidly dismutates to hydrogen peroxide, either spontaneously or facilitated by enzymes called superoxide dismutases. Endogenous hydrogen peroxide drives redox signaling, a molecular network of signal propagation that supports key aspects of wound healing such as cell migration, proliferation, and angiogenesis. Neutrophil-derived hydrogen peroxide may be utilized by MPO to mediate peroxidation of chloride ions, resulting in the formation of hypochlorous acid (HOCl), a potent disinfectant (see Fig. 13.12).

Three major factors may contribute to wound tissue hypoxia: (1) peripheral vascular diseases garroting O_2 supply; (2) increased O_2 demand of the healing tissue; and (3) generation of ROS by way of respiratory burst and for redox signaling.¹³⁷ Other related factors, such as arterial hypoxia (e.g., pulmonary fibrosis or pneumonia, sympathetic response to pain, hypothermia, anemia caused by major blood loss, cyanotic heart disease, high altitude), may contribute to wound hypoxia as well. Depending on factors such as these, it is important to recognize that wound hypoxia may range anywhere from near anoxia to mild to modest hypoxia. In this context it is also important to appreciate that point measurements performed in the wound tissue may not provide a complete picture of the wound tissue biology because it is likely that the magnitude of wound hypoxia is not uniformly distributed throughout the affected tissue, especially in large wounds. This is most likely the case in chronic wounds presented clinically as opposed to experimental wounds, which are more controlled and homogeneous in nature. In any single problem wound presented in the clinic, it is likely that there are pockets of near anoxia as well as that of different grades of hypoxia (Fig. 13.13). As the weakest link in the chain, tissue at the near-anoxic pockets will be vulnerable to necrosis, which in turn may propagate secondary tissue damage and infection. Pockets of extreme hypoxia may be flooded with hypoxia-inducible angiogenic factors but would fail to vascularize functionally because of insufficient O_2 that is necessary

to fuel the repair process. Indeed, uncontrolled expression of VEGF and its receptors leads to insufficient skin angiogenesis.¹³⁸ Whether cells in the pockets of extreme hypoxia are O_2 -responsive is another concern. Even if such cells may have passed the point of no return in the survival curve, correction of tissue oxygenation is likely to help clean up the dead or dying tissue and replace the void with proliferating neighboring cells. Pockets of moderate or mild hypoxia are likely to be the point of origin of successful angiogenic response as long as other barriers such as infection and epigenetic alterations are kept to a minimum.

Limited supply and high demand: the oxygen imbalance

Peripheral vascular disease can affect the arteries and the veins as well as the lymph vessels. The most common and important type of peripheral vascular disease is peripheral arterial disease, or PAD, which affects about 8 million Americans. The ankle brachial pressure index represents a simple noninvasive method to detect arterial insufficiency within a limb. Arterial diseases, especially those associated with diabetes, represent a major complicating factor in wound healing. PAD is the only identifiable etiology in approximately 10% of leg ulcers. In an ischemic limb, peripheral tissues are deprived of blood supply as PAD progresses, causing tissue loss, ulcers, and gangrene.

Venous insufficiency, on the other hand, is the root cause of most leg ulcers. Chronic venous insufficiency, characterized by the retrograde flow of blood in the lower extremity, is associated with changes in the venous wall and valves generally caused by inflammatory disorders induced by venous hypertension and associated fluid shear stress. Factors causing arterial hypoxemia may also limit O_2 supply to the wound tissue. Compromised pulmonary health, loss of hepatic function, hemodialysis, anemia, altitude hypoxemia, nitroglycerin therapy, nasal packing, critical illness, pain, and hypothermia

Fig. 13.13 Heterogeneous distribution of oxygen in the wound tissue: pockets of graded levels of hypoxia. Shade of blue represents graded hypoxia. Shade of red or pink represents oxygenated tissue. Tissue around each blood vessel is dark pink in shade, representing regions that are well oxygenated (oxygen-rich pockets). Bacteria and bacterial infection are presented by shades of green on the surface of the open wound.

are examples of conditions associated with arterial hypoxemia. Vasoconstricting drugs may contribute to tissue hypoxia as well.¹⁰³

Increased energy demand of the healing tissue leads to a hypermetabolic state wherein additional energy is generated from oxidative metabolism, increasing the O_2 demand of the healing tissue. Adenosine triphosphate (ATP) thus generated powers tissue repair. At the injury site, extracellular ATP may be contributed by platelets and other disintegrating cells. Extracellular ATP liberated during hypoxia or inflammation can either signal directly to purinergic receptors or, after phosphohydrolytic metabolism, can activate surface adenosine receptors. Purinergic signaling may influence numerous aspects of wound biology, including immune response, inflammation, vascular as well as epithelial biology. ATP may be immunostimulatory or vice versa, depending on extracellular concentrations as well as on expression patterns of purinergic receptors and ectoenzymes. Extracellular ATP induces receptor activation in epithelial cells. ATP, released upon epithelial injury, acts as an early signal to trigger cell responses, including an increase in heparin-binding epidermal growth factor (EGF)-like growth factor shedding, subsequent transactivation of the EGF receptor and its downstream signaling, resulting in wound healing. ATP released from the injured epithelial cells is now known also to turn on NADPH oxidases, the activity of which is critically required to produce the redox signals required for wound healing.¹³⁷ Human endothelial cells are rich in purinergic receptors and therefore responsive to extracellular ATP as well. ATP induces endothelium-dependent vasodilation. Both ATP as well as adenosine regulate smooth muscle and endothelial cell proliferation. Recognizing that hypoxia limits ATP synthesis in the ischemic wound tissue, therapeutic ATP delivery systems have been studied for their effect on wound healing. While these approaches may compensate for the deficiency of ATP *per se* in the ischemic wound tissue, they will fail to address the other essential functions of O_2 and its derivatives in wound healing, as discussed below.

Absolute requirements for O_2 arise in several points along the angiogenic sequence. For instance, all vessels require a net or sheath of ECM, mainly collagen and proteoglycans, to guide tube formation and resist the pressures of blood flow. Conditions for collagen deposition and polymerization can be created only if molecular O_2 is available to be incorporated into the structure of nascent collagen by prolyl and lysyl hydroxylases. Without the obligatory extracellular hydroxylated collagen, new capillary tubes assemble poorly and remain fragile.¹³⁹ This has a convincing clinical correlate in scurvy, i.e., ascorbate deficiency. Scurvy results from insufficient intake of ascorbate which is required for correct collagen synthesis in humans. Ascorbate is required for the post-translational hydroxylation of collagen that enables the matured collagen molecules to escape to the extracellular space and provide the necessary tensile strength. In scurvy, the collagenous sheath cannot form because, under ascorbate-deficient conditions, collagen cannot be hydroxylated. Consequently, new vessels fail to mature. Older vessels weaken and break, and wounds fail to heal. Thus, while hypoxia is a proved instigator of molecular signals for angiogenesis, it is also a proven enemy of vessel growth itself in non-tumor tissues. Collagen deposition proceeds in direct proportion to pO_2 across the entire physiologic range, from zero to hundreds

of mmHg. The K_m for O_2 for this reaction is approximately 25 and the V_{max} is approximately 250 mmHg, suggesting that new vessels cannot even approach their greatest possible rate of growth unless the wound tissue pO_2 is high.¹⁴⁰ Angiogenesis is directly proportional to pO_2 in injured tissues.^{141,142} Hypoxic wounds deposit collagen poorly and become infected easily, both of which are problems of considerable clinical significance.¹⁰³

Redox signaling

Additional high demand for oxygen is placed by a family of enzymes known as NADPH oxidases, which are known to be highly active at the wound site.¹⁴³ Recent work has identified that oxygen is not only required to disinfect wounds and fuel healing but that oxygen-dependent redox-sensitive signaling processes represent an integral component of the healing cascade.¹⁴² The widely held notion that biological free radicals are necessarily agents of destruction is now facing serious challenge.¹⁴³ Over a decade ago it was proposed that in biological systems oxidants are not necessarily always the triggers for oxidative damage and that oxidants such as H_2O_2 could actually serve as signaling messengers and drive several aspects of cellular signaling.¹⁴³ Today, that concept is much more developed and mature. Evidence supporting the role of oxidants such as H_2O_2 as signaling messengers is compelling.^{144–156}

Nitric oxide

At the wound site, NO is generated by an oxygen-dependent biosynthetic process. In the late 1970s, research was unfolding that implicated NO involvement in the process of vasodilation. By 1986, research culminated in the identification of NO as the endothelium-derived relaxing factor responsible for the maintenance of vascular tone, thus implicating NO as a potential wound-healing agent.¹⁵⁷ Maximal NO synthase activity is noted early in cutaneous wound healing, with sustained production up to 10 days after wounding. Wound macrophages represent a major source of NO production in the early phase of wound healing.¹⁵⁸ Inhibition of wound NO synthesis lowered wound collagen accumulation and wound-breaking strength, suggesting that NO synthesis is critical to wound collagen accumulation and acquisition of mechanical strength. Later it was demonstrated that wound fibroblasts are phenotypically altered during the healing process to synthesize NO, which, in turn, regulates their collagen synthetic and contractile activities.¹⁵⁹ The blockade of NO synthesis impairs cutaneous wound healing, acting in early and late phases of wound repair.¹⁶⁰ Interestingly, impaired diabetic wound healing is associated with decreased wound NO synthesis.¹⁶¹

microRNA and hypoxia response

Tissue injury is often associated with disruption of vascular supply to the injury site. Thus, the injured tissue often suffers from insufficient oxygen supply or hypoxia. Under conditions of additional underlying ischemia, hypoxia is severe and seriously limits wound healing.¹⁰³ Hypoxia induces specific miRNAs, collectively referred to as hypoxamirs.¹⁶² miRNA-210 is a classic hypoxamir. Expression of hypoxia-inducible factor 1 (HIF-1) is also controlled by specific miRNAs. In turn, HIF-1 controls the expression of hypoxamirs, which are

induced in the injured tissue.¹⁶³ Hypoxamirs are also induced by HIF-independent pathways. Although hypoxamirs generally favor angiogenesis, their metabolic and cell cycle arrest functions are in conflict with wound healing, especially in an ischemic setting. Silencing specific hypoxamirs may therefore represent a prudent approach to facilitate tissue repair. miRNA-210 represses mitochondrial respiration¹⁶⁴ and exaggerates production of undesired mitochondrial ROS.¹⁶⁴ These outcomes are not compatible with the higher energy demands associated with tissue repair. miR-210 also silences signaling via FGF¹⁶⁵ a key contributor to wound healing. The injured tissue is highly rich in ROS.¹⁶⁶ In addition, at the site of injury transition metal ions are released from a protein-bound state. Conditions such as these cause DNA damage which opposes tissue repair. DNA repair systems are therefore of key significance in enabling tissue repair. miR-210 antagonizes DNA repair.¹⁶⁶ This is another hypoxamir function that is in conflict with wound healing. Compatible with the common observation that ischemic wounds are refractory to healing response, elevated miRNA-210 in ischemic wounds attenuated keratinocyte proliferation and impaired wound closure.^{86,167}

miR regulation of angiogenesis

In 2005–2008, the first series of observations establishing key significance of miRNAs in the regulation of mammalian vascular biology came from experimental studies involved in arresting miRNA biogenesis to deplete the miRNA pools of vascular tissues and cells.¹⁶⁸ Dicer-dependent biogenesis of miRNA is required for blood vessel development during embryogenesis. Mice with endothelial cell-specific deletion of Dicer, a key enzyme supporting biogenesis of miRNAs, display defective postnatal angiogenesis. NADPH oxidase-derived ROS drive wound angiogenesis. Endothelial NADPH oxidase is subject to control by miRNAs.¹⁶⁹ Hypoxia is widely recognized as a cue that drives angiogenesis as part of an adaptive response to vascularize the oxygen-deficient host tissue. Hypoxia-induced repression of miR-200b is involved in such induction of angiogenesis by directly targeting GATA2, VEGFR2 and Ets-1.^{170,171} Various aspects of angiogenesis, such as proliferation, migration, and morphogenesis of endothelial cells, can be regulated by specific miRNAs in an endothelial-specific manner. miRNAs known to regulate angiogenesis *in vivo* are referred to as angiomiRs.¹⁷² miRNA-126 is specific to endothelial cells and regulates vascular integrity and developmental angiogenesis. Manipulating angiomiRs in the setting of tissue repair represents a new therapeutic approach that could be effective in promoting wound angiogenesis.

Impaired resolution of inflammation

The inflammation stage of wound healing is meant to be transient and self-resolving for healing to proceed normally. Temporally and spatially controlled mechanisms tightly control wound inflammation and resolution and these include removal of apoptotic neutrophils by functional macrophages. In patients with diabetes, elevated blood glucose levels results in glycosylation of phosphatidyl serine receptors on macrophages, which blocks recognition of apoptotic cells. This ineffective efferocytosis (phagocytosis of apoptotic cells) by wound macrophages results in increased production of pro-inflammatory cytokines such as TNF- α , IL-1 α , β and IL-6¹⁷³ and impaired resolution of inflammation.³⁹

miR regulation of inflammation

Disruption of miRNA biogenesis has a major impact on the overall immune system. Emerging studies indicate that miRNAs, especially miR-21, miR-146a/b, and miR-155, play a key role in regulating several hubs that orchestrate the inflammatory process.^{174,175} miRNAs have been directly implicated in the pathogenesis of inflammatory diseases such as osteoarthritis and rheumatoid arthritis. Resolvin-regulated specific miRNAs target genes involved in resolution of inflammation to establish a novel resolution circuit involving RvD1 receptor-dependent regulation of specific miRNAs.¹⁷⁶ Macrophage specific miR-21 induction was recently shown to promote an anti-inflammatory phenotype by down-regulating PTEN and PDCD4 resulting in elevated production of the anti-inflammatory cytokine IL-10.¹⁷⁷ miR-21 is efferocytosis-inducible in macrophages regulating a switch to an anti-inflammatory phenotype promoting resolution of inflammation. Furthermore, the brain-specific microRNA-124 can tame inflammation by turning off activated microglial cells and macrophages.¹⁷⁸ Of relevance to tissue repair is also the regulatory loop where cytokines, including those elicited following injury, are regulated by miRNAs, as well as regulate miRNA expression.^{179,180}

Stem cells

The regenerative potential of injured adult tissue suggests the physiological existence of cells capable of participating in the reparative process. The epithelium of the skin, the epidermis, is in a continuous equilibrium of growth and differentiation and has the remarkable capacity to self-renew completely, which relies on reservoirs of stem cells. In mammals, there are two broad types of stem cells: embryonic stem cells (ESCs) that are isolated from the inner cell mass of blastocysts, and adult stem cells that are found in various tissues. In adult organisms, stem cells and progenitor cells act as a repair system for the body, replenished in adult tissues. Stem cells have the property of self-renewal without differentiation and have the potential to differentiate into any type of cell. Totipotent stem cells have the ability to give rise to a whole organism due to their ability to differentiate into embryonic and extraembryonic cells. Pluripotent stem cells are derived from totipotent cells and can differentiate into all cell types but cannot give rise to a new organism (Fig. 13.14). ESCs are derived from the developing embryo, usually from the inner cell mass of a blastocyst or earlier morula stages. Lost or damaged cells can be replaced by differentiation, dedifferentiation, or transdifferentiation (Fig. 13.15). Recent advances have shown that the addition of a group of genes can not only restore pluripotency in a fully differentiated cell state (differentiation) but can also induce the cell to proliferate (dedifferentiation) or even switch to another cell type (transdifferentiation). Dedifferentiation is represented by a terminally differentiated cell reverting back to a less-differentiated stage from within its own lineage. This process allows the cell to proliferate again before redifferentiating, leading to the replacement of those cells that have been lost. Transdifferentiation is another naturally occurring mechanism that takes dedifferentiation a step further and sees cells regressing to a point where they can switch lineages, allowing them to differentiate into another cell type. Furthermore, reprogramming

Fig. 13.14 Stem cell renewal.

aims to revert differentiated cells to pluripotency. From here, they can differentiate into almost any cell type. Although reprogramming occurs naturally during fertilization to produce totipotent cells that can differentiate into any cell type, it has not yet formally been shown to be a genuine regenerative response. Furthermore, reprogramming side-steps the necessity of using embryos for regenerative therapies by using differentiated cells taken from a patient. From a clinical perspective, this comes with the additional bonus of circumventing the immunological problems such as transplant rejection and graft-versus-host disease associated with engraftment.¹⁸¹

The bone marrow (Fig. 13.16), home of stem and progenitor cells, contributes a significant proportion of cells in the skin.

Fig. 13.15 Stem cell differentiation, dedifferentiation, and transdifferentiation

The normal skin has long been known to contain bone marrow-derived cells that are involved in host defense and inflammatory processes, including wound healing. However, recent studies demonstrate that the bone marrow contributes not only inflammatory cells, but also keratinocytes and fibroblast-shaped cells to the skin. Similar to leukocytes in trafficking, stem/progenitor cells derived from the bone marrow could home to injured tissues and participate in the repair/regeneration. Moreover, culture-expanded bone marrow-derived MSCs have been shown to promote the healing of diabetic wounds, implying a profound therapeutic potential for skin defects such as chronic wounds and burns.¹⁸²

During the inflammatory phase, leukocytes migrating to the wound site are hematopoietic cells derived from the bone marrow. In the skin the bulge of the hair follicle (Fig. 13.17) plays a role as a reservoir of stem cells. In mice it has been shown that the bulge region contains hematopoietic cells that are identical to the bone marrow-derived cells and also to those found in fetal circulation.¹⁸³ Moreover this region also serves as a reservoir for precursors of mast cells. Discovery of these epidermal stem cells in the hair follicle bulge led to the hypothesis that these cells are necessary for both epidermal renewal as well as wound healing.^{184,185} It was shown that cells from the bulge do not contribute to epidermal regeneration;

Fig. 13.16 Bone marrow stem cells. CNS, central nervous system.

Fig. 13.17 Stem cells in the epidermis. Hair follicles act as reservoirs of stem cells in the skin. **(A)** Cross-sectional view of a hair follicle. The matrix stem cells differentiate into various parts of the hair while the long-term stem cells are present in the bulge region. The stem cells from the bulge maintain the sebaceous gland and epidermal stem cells. **(B)** A mammalian gut crypt. Stem cells are located at the basal region with the Paneth cells. The transit amplifying (TA) cells are stem cell progeny which move upwards and differentiate.

however, upon injury cells from the bulge are recruited into the epidermis and migrate in a linear manner toward the center of the wound.¹⁸⁵ These cells were noted to be transient, living only for a few weeks, thus representing an acute response to injury.

There are two main branches of stem cells in the bone marrow, including hematopoietic stem cells (HSCs) and MSCs. Adult bone marrow-derived HSCs have long been recognized as a precursor to all blood cell lineages, including erythrocytes, platelets, and white blood cells. Additionally, HSCs may also give rise to fibrocytes and endothelial progenitor cells. Circulating endothelial precursor cells play a role in neovascularization which is essential for healing.^{186,187} Bone marrow-derived stem cells also contribute to the deposition of collagen III in the wound¹⁸⁸ and differentiate into fibroblasts,¹⁸⁹ keratinocytes,¹⁹⁰ and fibrocytes.¹⁹¹ Bone marrow-derived MSCs, which are also referred to as bone marrow mesenchymal stromal cells or marrow stromal cells, are self-renewing and expandable stem cells. Although present as a rare cell population in the bone marrow,

representing about 0.001–0.01% of the nucleated cells, about 10-fold less abundant than HSCs, MSCs are expandable in culture and multipotent, capable of differentiating into several cell types.

Because of their properties of regeneration and differentiation, the use of stem cells to heal problem wounds has long been of interest. Indeed, autologous bone marrow aspirates and cultured cells were helpful in healing chronic wounds.¹⁹² In the case of burn wounds, bone marrow-derived stem cell treatment shows promise as well.¹⁹³ Another major source of adult stem cells is adipose tissue.¹⁹⁴ The capability of adipose-derived adult stem cells to differentiate into bone, muscle, fat, or cartilage, or into cells of mesenchymal lineage, makes them a prime target for therapeutic use. It has been shown that adult stem cells enhanced wound healing in a murine model.^{195,196} However, a caveat to the indiscriminate use of autologous stem cell therapy in wound healing, particularly in the diabetic population, was revealed in a recent study that demonstrated that diabetic adipose-derived stem cells (ASCs) are compromised in their ability to initiate vascularization and ineffective in wound healing.¹⁹⁷

Hair follicles are an integral part of mammalian skin where they help the epidermis to maintain the body's protective barrier against its external environment. With rare exceptions (such as palms and eyelids), hair follicles are present all over the skin and play an important role in physiological tissue renewal and regeneration after injury. Hair follicles represent an autonomous miniorgan, which provides an excellent model system for studying the biology of adult stem cells.¹⁹⁸ There are obvious differences between human and mouse skin, yet the knowledge gained from lineage-tracing experiments in mice has greatly expanded our understanding of the cellular behavior of the different keratinocyte populations during physiological and injury-induced tissue regeneration. As in most of the body's organs, the skin experiences constant renewal. The upper keratinized layer of the interfollicular epidermis, which consists of terminally differentiated cells, is shed and replaced by cells originating from the actively proliferating layer beneath. In contrast, hair follicles undergo cycles of growth (anagen) and rest (telogen). The potential for proliferation to sustain the lifelong replenishment of normal cell loss and to repair occasional tissue damage lies within the population of epidermal stem cells. The hair follicle bulge harbors stem cells that may help in renewal and repair of the skin. The term "bulge", originally called "*der Wulst*", was introduced in 1903 by a German morphologist, P. Stöhr, to describe an eminent structure at the site of attachment of the arrector pili muscle in human hair follicles.¹⁹⁹ Similar to many other somatic stem cells, bulge cells are slow-cycling in nature. This feature has permitted their initial identification and isolation as label-retaining cells that can retain a pulse of nucleotide label following a long chase period and is frequently regarded as a defining characteristic of the hair follicle stem cell. In addition, the availability of several immunohistochemical markers, including keratin-15 and CD34, that specifically label murine follicular stem cells has given researchers the ability to examine carefully the signals required for adult stem cell activation and renewal. We now know that the bulge serves as a repository of long-lived multipotent stem cells, imparted with the capacity to differentiate into all cell types that constitute the lower cyclic portion of the hair follicle, as well as the interfollicular epidermis during wound repair.^{198–200}

Although research into the use of stem cells for regenerative medicine is on a steep upward slope, clinical success has not been as forthcoming. This has been primarily attributed to a lack of information on the basic biology of stem cells, which remains insufficient to justify clinical studies. Since most clinical protocols use intravenous application of MSCs, it has become important to understand their trafficking in the blood stream. Moreover, since relatively little is known where the transplanted MSCs might locate, a better understanding of involved homing mechanisms will likely shed light on how MSCs exert their therapeutic effects. For instance, it is unclear whether mechanisms used at injured sites are location-specific or whether this recruitment can be modulated for therapeutic purposes. In addition, it has recently been suggested that platelets may play an important role in stem cell recruitment to sites of injury. A better understanding of the mechanisms used by stem cells during tissue homing would allow us to develop strategies to improve recruitment of these rare cells.²⁰¹

Induced pluripotent stem cells

Pluripotent stem cells possess the unique property of differentiating into all other cell types of the human body. The discovery of induced pluripotent stem cells (iPSCs) in 2006 has opened up new avenues in clinical medicine.^{202,203} Recent breakthrough studies using a combination of four factors to reprogram human somatic cells into pluripotent stem cells without using embryos or eggs have led to an important revolution in stem cell research. It is now possible to convert somatic cells, such as skin fibroblasts and B lymphocytes, into pluripotent stem cells that closely resemble ESCs. Recently, functional neurons, cardiomyocytes, pancreatic islet cells, hepatocytes, and retinal cells have been derived from human iPSCs, thus reconfirming the pluripotency and differentiation capacity of these cells. These findings further open up the possibility of using iPSCs in cell replacement therapy for various disorders, including chronic wounds.

miRNA regulation of stem cells

Endogenous miRNA-binding sites have been identified in murine embryonic stem cells (ESCs). miRNAs govern ESC function by serving as control hubs managing regulatory networks. A central importance of such governance is highlighted by the observation that ESCs lacking miRNAs lose their “stemness”. ESCs with deficient miRNA biogenesis systems switch to a mode of ongoing cell division. They do not differentiate on demand because of failure to turn off the pluripotency regulatory program.²⁰⁴ miRNAs conduct the orchestra of critical gene regulatory networks controlled by pluripotency factors within stem cells. Individual miRNA-dependent pathways that promote the reprogramming of somatic cells into iPSCs have now been identified. Manipulation of specific cellular miRNAs helps enhance reprogramming of somatic cells to an ESC-like phenotype, helping to generate iPSCs.²⁰⁵ Expression of miRNAs is also subject to control by epigenetic factors.^{83,206} Such control influences the balance between proliferation and differentiation of stem cells. In executing such control, the miRNA element of epigenetics cross-talks with changes in chromatin structure as well as with changes in DNA methylation. Collectively, this provides for a mechanism by which the tissue injury

microenvironment can influence miRNA-dependent reparative and regenerative processes.

Non-invasive wound measurements

Laser speckle flowmetry

Functional assessment of wound vascularization is made possible by the application of the laser speckle imaging technology which provides dynamic response and spatial resolution resulting in both real-time graphs and video recordings of the area of interest. The speckled patterns (dark and bright areas) generated by the instrument reflect the degree of movement in the area under consideration. Blurring in the speckle patterns indicates motion of the particles in the blood. Blurred (in motion) areas therefore can be contrasted from those without blurring (no motion) and color coded to generate perfusion maps. It is therefore a powerful approach for blood perfusion imaging. Laser speckle imaging has been used for the assessment of spatio-temporal hemodynamic changes during excisional and burn wound healing.^{207–209} Shown in Fig. 13.18 are longitudinal measurements of perfusion changes in the entire wound area as healing progressed for a period of six weeks. The increased perfusion along the wound edge during early stages of wound healing reflect initial vasodilation (day 3) followed by neovascularization, which gradually moves towards the wound bed (days 21–42) as resolution occurs along the edge.

High resolution harmonics ultrasound imaging

Modern ultrasound systems have been applied to vascular imaging, visualizing 3D structures in motion and measuring the stiffness of tissues. For the skin, higher spatial resolution can be obtained with low frequency sound waves which allow the differentiation of the epidermis, dermis and subcutaneous fat and the muscle layers. Using the color Doppler imaging (CDI) application, longitudinal imaging of functional blood flow parameters in a gated peripheral feeder artery supplying the wound site were visualized for the first time indicating a bimodal pattern of arterial hemodynamics throughout the process of wound healing (Fig. 13.19). Additionally, B-mode imaging and elastography of wound areas have provided 3D visualization and measurement of wound depth, cavities/tunnels, scar formation and mechanical features of the wound that would otherwise go undetected by current clinical standards.²⁰⁹

Transepidermal water loss (TEWL)

The TEWL measurement is a reliable indicator of skin barrier function²¹⁰ and is an important parameter to consider for skin health and function. TEWL measurements indicate the quantity of water that passes from inside a body through the epidermal layer to the external environment via diffusion and evaporation processes. These can be influenced by humidity, temperature, hydration status of the skin, etc., and should be interpreted cautiously. Increased TEWL measurements could indicate loss or impairment of barrier function indicating that such skin is not only vulnerable to loss of

Fig. 13.18 Laser speckle perfusion imaging shows dynamic changes in wound-site blood flow over time. (Reproduced from Gnyawali S, Barki KG, Mathew-Steiner SS, et al. High-resolution harmonics ultrasound imaging for non-invasive characterization of wound healing in a pre-clinical swine model. Plos One, 2015;10:e0122327.)

moisture but is now a portal of entry for microbes and other irritants. Recent evidence from preclinical studies emphasizes the need for functional assessments of wound closure using measurements such as TEWL. Biofilm-infected wounds that appeared visually closed showed high TEWL readings indicating functional barrier failure which was then linked to the downregulation of critical cellular tight junction proteins (ZO-1 and ZO-2) by biofilm-induced microRNAs (miR-146a and miR-106b).¹¹³

Hyperspectral imaging

This technique is a non-invasive, non-destructive, chemical-free assessment that provides maps of oxygenated tissue

allowing qualitative and quantitative measurements with high spectral resolution. A combination of a highly sensitive charge-coupled device (CCD) and infrared (IR) cameras detect dynamic changes of tissue hemoglobin concentration and temperature distribution in response to vascular occlusion and reperfusion resulting in oxygenation maps. The OxyVu-2 software is used to perform imaging analysis that allows post-processing of the hyperspectral images for tissue oxygenation (StO_2). This imaging method has been used to characterize the hypoxia component of tissue ischemia in a mouse model¹⁶⁷ and in combination with laser speckle and thermal imaging modalities, it has been applied to studies on normal human subjects following post-occlusive, reactive hyperemia procedures.²¹¹

Fig. 13.19 Ultrasound measurement of pulse pressure indicates enhanced blood flow via feeder artery supplying the edge of the wound. (Reproduced from Gnyawali S, Barki KG, Mathew-Steiner SS, et al. High-resolution harmonics ultrasound imaging for non-invasive characterization of wound healing in a pre-clinical swine model. Plos One, 2015;10:e0122327.)

Near infrared thermal imaging

IR thermography is a technique suited to non-invasive imaging of inflammation in tissue. A thermal imaging camera, Thermovision™ model A40, is used to capture and record thermal distributions and variations in real-time, *in vivo*, as an indicator of inflammation. The sensitivity of the camera allows the detection of changes as small as 0.02°C. The ResearchIR software allows high speed recording and advanced post-processing of fast-changing thermal

events. Thermography has been applied to diabetic foot and pressure ulcers to identify latent inflammation. The increased temperature measured in these types of wounds could indicate inflammation or other factors that impair wound healing. In combination with laser speckle and hyperspectral imaging, thermographic imaging has been used in a multimodal imaging format to continuously monitor the wound-healing process in a clinical trial, demonstrating its clinical applicability in wound-healing assessment.²¹¹

Clinical wound management

Clinical vignette – acute wounds and elective surgical patients

Diagnosis/patient presentation

The preoperative evaluation should include a thorough medical history, a social history that includes determining who or how wound care or postoperative care will be provided, pulse exam if the wound is on the lower extremity, and a nutritional assessment. If the patient is diabetic, then hemoglobin A1c should be checked. Protein synthesis, especially collagen, is essential to healing and pre-albumin is a good basic indicator of protein synthesis capacity. However, it is an acute phase reactant, so it will be depressed during concomitant episodes of sepsis or other generalized inflammatory response. To address this, pre-albumin levels can be followed serially as often as 2 times per week (half-life is 2 days compared to albumin with a half-life of 20 days) as it should rise as the inflammatory state subsides or with initiation of protein supplementation. The steady state pre-albumin value is an indicator of the patient's nutritional status and has been shown to correlate with clinical outcomes.²¹²

Patient selection

Every surgical patient is a wound patient once the scalpel cuts the skin. The prudent surgeon will optimize conditions for good wound healing and surgical outcomes by preparing the patient *and the wound bed* for surgical closure.

Treatment (wound-healing specific)

- If protein malnutrition is present it is reasonable to assume other nutritional factors are also depleted. Multivitamin and essential element supplementation should be included in the nutritional optimization plan.
- For patients on a chronic glucocorticoid medication regimen, vitamin A supplementation can overcome some of the detrimental effects of these steroids on wound healing.²¹³ It can be given for 2 weeks typically at 10 000 IU per day and should be started immediately postoperatively for surgical patients.
- Optimize glucose control depending on results of hemoglobin A1c or blood glucose monitoring. Elective cases should be postponed in patients with poorly controlled diabetes as there is abundant literature indicating the poor surgical and wound-healing outcomes associated with poor glucose control.
- Debridement must be adequate to remove all devitalized or infected tissue otherwise it delays progression from the inflammatory to the proliferative phase of wound healing (see section on inflammatory phase).
- All open wounds must be examined by probing with a finger and if not possible then a cotton tip applicator to make sure there are no foreign bodies, underlying bony injuries, or fistulous tracts.
- Wound beds must be free of infection prior to closure or have ongoing treatment for infection at the time of surgical closure to prevent wound recurrence. Weekly wound debridement is a good clinical practice to achieve this objective.
- Optimize perioperative tissue perfusion conditions for good wound healing outcomes* – the following recommendations are supported by level 1 evidence and are especially useful for flap patients.
 - Maintain normothermia ($\geq 36^{\circ}\text{C}$) intraoperatively – significantly decreases the rate of postoperative wound infection²¹⁴
 - Provide adequate fluid resuscitation intraoperatively and postoperatively – increases tissue oxygenation and capillary blood flow.²¹⁵ For open laparotomy cases patients were given 16–18 ml/kg per hour during surgery.
 - Perioperative administration of supplemental oxygen, such as 0.8 fraction of inspired oxygen (FiO_2) given intraoperatively and 2 hours postoperatively, is sufficient to significantly decrease postoperative infection rates, length of stay, and mortality. However, *these results can only be achieved when the patient is normothermic and adequately perfused/intravascularly replete.*²¹⁶

Outcomes/prognosis/complications

- The expected outcome for a wound that heals by primary intent is that the incision is sealed by 24–48 hours because of fibrin deposition in the wound. At that point the wound progresses to the proliferative phase of healing.
- The prognosis for an uncomplicated wound that heals by primary intent is that the incision will acquire tensile strength at the following rate: 10% at 2 weeks, 30% at 4 weeks and 80% at 6 weeks compared to intact normal skin. Maximal tensile strength of the incision is achieved at 6 weeks after closure and thus never achieves the same tensile strength as intact skin.²¹⁷
- Infection is a common and highly undesirable complication for wounds or surgical procedures. The expected rate of surgical site infection²¹⁸ can be roughly estimated using the wound classification as defined by the Centers for Disease Control.
 - Class I/Clean – An uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital, or uninfected urinary tract is not entered. In addition, clean wounds are primarily closed and, if necessary, drained with closed drainage. **Expected infection rate: 1–2%**
 - Class II/Clean-contaminated – An operative wound in which the respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina, and oropharynx are included in this category, provided no evidence of infection or major break in technique is encountered. **Expected infection rate: 3%**
 - Class III/Contaminated – Open, fresh, accidental wounds. In addition, operations with major breaks in sterile technique (e.g., open cardiac massage) or gross spillage from the gastrointestinal tract, and incisions in which acute, non-purulent inflammation is encountered are included in this category. **Expected infection rate: 6%**
 - Class IV/Dirty-infected – Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera. This definition suggests that the organisms causing postoperative infection were present in the operative field before the operation. **Expected infection rate: 7–13%**
- Risk factors for surgical site infection²¹⁹ include:
 - Patient characteristics
 - Age
 - Obesity
 - Smoking
 - Diabetes
 - Nutritional status
 - Colonization with microorganisms
 - Altered immune response
 - Co-existing infections at a remote body site
 - Length of preoperative stay
 - ≥ 3 diagnoses at the time of discharge

- b. Operative characteristics
 - i. Abdominal operation
 - ii. Operation lasting longer than 2 hours
 - iii. Wound class III or IV
- c. Surgical technique
 - i. Poor hemostasis
 - ii. Failure to obliterate dead space
 - iii. Tissue trauma
- 5. Incision dehiscence/wound recurrence – occult biofilm infection (see [miR regulation of skin barrier functions](#))
 - a. Determination of wound closure – the skin as an organ has 3 primary functions: thermoregulation, prevention of evaporative water loss, and to serve as a barrier to infections. Wounds that have occult biofilm infection will appear closed, but the skin will be functionally defective with elevated levels of transepidermal water loss (TEWL – see non-invasive imaging modalities). Channels in the cells that let water out of the skin will also let bacteria into the skin. The finding of elevated TEWL is most likely to occur in the clinical setting of surgical closure of wounds with pre-existing biofilm infection.
 - b. Unrecognized soft tissue or bony infection, especially occult biofilm infection, is a suspected cause for a significant number of flap dehiscence/wound recurrence outcomes. Biofilm-producing bacteria express high levels of ceramidase that enzymatically digests skin lipids.²²⁰ Adjunctive therapy with topical antibiotics or biofilm-inhibiting dressings (see section on [Electroceuticals](#)) at the time of debridement along with systemic antibiotics may mitigate the risk for postoperative biofilm infection.
 - c. Measurement of C-reactive protein and erythrocyte sedimentation rate can be used to screen for osteomyelitis preoperatively (if elevated, confirm diagnosis with imaging studies). Serial measurements with an anticipated decrease in these inflammatory markers can be used to monitor response to therapy.

*Hints and tips – One way to optimize postoperative conditions for successful flap surgery is using the following regimen: maintenance IV at 2 ml/kg/hr and 4 liter oxygen per nasal cannula for 24 hours postoperatively. Keep the room warm (if in a single room) with the temperature set at 80°F (26.6°C) or keep patient covered and warm until discharge. This promotes vasodilation, optimal perfusion and O₂ delivery to the flap. It will also increase collagen deposition for wound healing and decrease risk for infection.

Clinical vignette – diabetic foot ulcer (DFU)

Diagnosis/patient presentation

Patients with diabetic foot ulcers commonly present with a classic triad of clinical findings: ischemia, neuropathy and foot deformity. The ulcers are frequently initiated by local trauma where the patient cannot sense the injurious event because of underlying sensory neuropathy. For this reason diabetics are instructed never to go barefoot. Pressure from poorly fitting footwear because of foot deformity is another common initiating event. An early sign of pressure on the foot is the development of a callus, which should be interpreted as impending foot ulceration if there is no intervention to off-load the pressure. Development of foot deformity is attributable to several factors. Neuropathy contributes to the development of Charcot changes in the midfoot with osteopenia, fractures/dislocations, and collapse of the arch. The metatarsal heads become prominent with extension of the toes at the metatarsal phalangeal joints because of motor neuropathy of the intrinsic foot muscles ([Fig. 13.20](#)). Elevated glucose levels cause glycosylation of the Achilles tendon that limits excursion. There is decreased range of motion with foot dorsiflexion, which affects gait mechanics. Normally there is a heel strike and then rolling up onto the ball of the foot as a person progresses through their stride. The loss of foot dorsiflexion results in a foot strike that is more like a peg with the forefoot absorbing more of the impact during the stride than normal thereby leading to forefoot ulceration. The risk for forefoot ulceration is increased when metatarsal heads are prominent. The combination of elevated glucose and diseased vaso nervorum is thought to be responsible for the motor and sensory neuropathies that are observed in these patients, but it also affects autonomic nerves. There is loss of vasomotor regulation, arteriovenous shunting, and when combined with microangiopathy (thickened basement membrane, thrombosis) results in ischemia at the areas of tissue injury. This means that a patient can present with a pink foot with palpable pulses and a wound that is actually not well perfused.

Patient selection

Prior to any non-emergent surgical procedure, patients should have hemoglobin A1c checked and glucose control optimized. All patients need a thorough vascular exam to determine whether there is adequate blood flow to the foot to support wound healing prior to any bedside debridement or non-emergent operative surgical procedures. Patients with inadequate blood flow need revascularization to achieve a closed wound.

Treatment

1. Deformity – off-loading interventions are an essential part of any treatment plan and can include
 - a. Complete non-weight bearing – e.g. crutches or wheelchair
 - b. Total contact casting – not removable and changed weekly by a healthcare professional
 - c. Removable cast walker – e.g., walking boot, cast shoe
 - d. Modified footwear – required to heal and prevent ulcerations in patients with foot deformity, refer to podiatrist for evaluation
2. Infection – risk for infection increases the longer the wound is open
 - a. Glucose control is essential – poor glycemic control results in impaired macrophage function, inability to resolve inflammation (see section on [resolution of inflammation](#)) and an open wound stalled in the inflammatory phase of healing
 - b. Osteomyelitis
 - i. If bone is exposed, the likelihood of infection/osteomyelitis is 80%
 - ii. Infected bone should be debrided
 - c. Biofilm – bacteria in a biofilm state are tightly adherent to the wound surface
 - i. If bone is exposed the bacteria will adhere to bone causing osteomyelitis that cannot be treated with antibiotics alone. Surgical debridement along with antibiotics is required to eradicate the infection.*
 - ii. The presence of biofilm will result in a chronic open wound – debridement disrupts biofilm, but it will recur,¹¹³ therefore good clinical practice is weekly debridement
3. Ischemia – there must be adequate blood flow to support wound healing
 - a. Diagnosis
 - i. Ankle-brachial index with pulse waveforms – must include pulse waveforms as index values can be falsely elevated because of atherosclerotic disease of the arteries (ABI >1.2)
 - ii. Toe-brachial index – detects vascular obstruction distal to the ankle, should be used for all ulcers located on the

foot and should include pulse waveforms. Adequate perfusion is a TBI >0.6

- iii. Transcutaneous oxygen measurement (TcOM) – closest measurement of tissue perfusion near wound. It gives absolute values of tissue oxygenation in mmHg, so results are easy to interpret. Adequate perfusion is ≥ 30 mmHg
- iv. Skin perfusion pressure – occludes blood flow and measures the opening pressure at which perfusion first returns to the cutaneous microcirculation after controlled release of the occlusion. It combines the use of a laser Doppler and a pressure cuff. Adequate perfusion is ≥ 30 mmHg
- v. Angiography – may miss occlusion of perforators off axial vessels in the lower extremity
- vi. Laser speckle – provides a dynamic image of blood flow

b. Treatment

- i. Surgical revascularization
- ii. Stenting – for smaller vessels below the knee just need patency long enough to get wound healed
- iii. Hyperbaric oxygen (HBO) – can be used for patients who are not candidates for surgical revascularization or in preparation for flap or graft

4. Surgical interventions

- a. Weekly bedside debridement is associated with improved healing outcomes²²¹
- b. Achilles tendon lengthening will promote healing of forefoot ulcers in patients with less than 10 degrees of passive ankle dorsiflexion with the knee flexed and extended^{222,223}
- c. Successful surgical closure with a flap or graft can be achieved when the wound bed is free from infection, the wounded area on the foot is appropriately off-loaded, there is adequate blood supply to support healing, and the patient is nutritionally replete with good glucose control.

5. Advanced therapies

- a. HBO – stimulates angiogenesis and eradicates infection from specific pathogens. Patients with DFU that qualify for HBO treatment are Wagner grade 3 or higher AND have failed to improve after at least 30 days of standard therapy. Meta-analysis indicates that for every 4 patients treated with HBO, 1 major amputation, i.e. below-knee or above-knee amputation, would be prevented.²²⁴
- b. Engineered skin – e.g. Apligraf® or Dermagraft®
- c. Extracellular matrix products – e.g. Promogran Prisma®
- d. Growth factors
 - i. Recombinant platelet derived growth factor-BB – Regranex™ is the FDA-approved version of the growth factor indicated for use in diabetic foot ulcers. However, it was given a boxed warning by the FDA in 2008 for an increased risk of malignancies observed distant to the site of application in patients treated with 3 or more tubes. It is no longer used and serves as a reminder of the potential off-target effects of growth factors.
 - ii. Autologous platelet gel (APG) is a cell-based therapy that delivers growth factors and cytokines to the wound through topical application to the wound bed. The data

is mixed regarding APG efficacy and level 1 evidence is not available. The challenge with APGs is titrating the level of growth factor and cytokine release to have it fall within a therapeutic range.

Outcomes/prognosis/complications

1. Validated diabetes foot ulcer severity scores^{225,226}

- a. Wagner grade
 - i. Grade 0: No open lesions; may have deformity or cellulitis
 - ii. Grade 1: Superficial ulcer, partial or full-thickness
 - iii. Grade 2: Ulcer extension to ligament, tendon, joint capsule, or deep fascia; no abscess or osteomyelitis
 - iv. Grade 3: Deep ulcer with abscess, osteomyelitis, tendonitis or joint sepsis
 - v. Grade 4: Gangrene localized to portion of forefoot or heel
 - vi. Grade 5: Total foot gangrene
- b. University of Texas – stage is the more sensitive prognostic indicator
 - i. Stages
 - I. Stage A: No infection or ischemia
 - II. Stage B: Infection present
 - III. Stage C: Ischemia present
 - IV. Stage D: Infection and ischemia present
 - ii. Grading
 - I. Grade 0: Epithelialized wound
 - II. Grade 1: Superficial wound
 - III. Grade 2: Wound penetrates to tendon or capsule
 - IV. Grade 3: Wound penetrates to bone or joint

2. Prognosis

- a. Correlates with ulcer severity – worse prognosis, e.g. time to heal and risk for amputation, with increasing severity
- b. The average diabetic foot ulcer is open for 12 months
- c. Presence of end stage renal disease (ESRD) worsens prognosis

3. Complications – amputation is the feared complication. The prognosis for patients getting amputations is worse than many types of cancer. Amputation is considered preventable by CMS if patients receive good foot care and it is used as a quality indicator for population-based healthcare.

- a. 80% of amputations in patients with diabetes mellitus are preceded by foot ulceration
- b. Survival rate after below-knee amputation
 - i. Without ESRD: 1 year = 72.5% and 5 year = 35%
 - ii. With ESRD: 1 year = 54.6% and 5 year = 16%
- c. Survival rates for diabetic patients after above knee amputation
 - i. Without ESRD: 1 year = 48% and 5 year = 16%
 - ii. With ESRD: 1 year = 26.8% and 5 year = 8.2%

*Hints and tips – Use resorbable antibiotic-impregnated beads in the wound after resection of infected bone to achieve a sustained release of high levels of antibiotics directly at the site to prevent recurrent biofilm infection, osteomyelitis and flap dehiscence (Fig. 13.21). A common approach is to use 1 g vancomycin and 1.2 g tobramycin mixed in with the bead material (Stimulan®, Novartis). Serum levels should be checked postoperatively and if levels are significantly elevated irrigate through a closed suction drain to get the beads to dissolve.

Clinical vignette – venous leg ulcer (VLU)**Diagnosis/ patient presentation**

VLU are present in 1% of the population.⁵ Important antecedent events are a history of major lower extremity trauma, deep vein thrombosis (DVT), varicose veins, and obesity. VLU are caused by incompetence of the venous valves in the leg resulting in a static column of blood pooling in the lower extremity. The venous hypertension causes an increase in the number of dermal capillaries in the skin with increased capillary pressure and increased capillary permeability. This leads to extravasation and perivascular deposition of blood and fibrinogen/fibrin. The fibrin barrier prevents oxygen diffusion out of the capillary beds into the surrounding soft tissues resulting in ischemia, lipodermatosclerosis, and ulceration.²²⁷ Tissue affected by lipodermatosclerosis is stiff, friable, ischemic, and heals poorly. Patients will complain of aching, itching, heaviness, tightness, pain or muscle cramps. The ulcers are superficial with irregular borders, usually located near the medial malleolus with surrounding hemosiderin deposits and lipodermatosclerosis. There may be copious drainage from the ulcers as well. The diagnosis of VLU can be confirmed with non-invasive vascular studies. Duplex ultrasound with proximal compression of the vein or Valsalva maneuver to look for venous reflux is the gold standard for diagnosis with plethysmography as an alternative method if reflux studies are inconclusive. Venography, helical venous CT and MR have also been used to establish the diagnosis. Patients with VLU have an increased risk for thrombotic events, especially with a personal or family history of thrombotic events, early onset VLU prior to age 50, and recurrent or recalcitrant VLU.^{228,229}

Patient selection

All patients must be evaluated for peripheral artery disease, which is present in at least 30% of patients with VLU. The presence of peripheral artery disease changes the management of patients with VLU. The Society for Vascular Surgeons and American Venous Forum recommend laboratory evaluation for thrombophilia in patients with a history of chronic or recurrent VLU.²³⁰

Treatment

It is important to remember the VLU is the symptom and the disease is venous valvular incompetence. Treatments directed toward the ulcer will not cure the disease.

1. Compression is the mainstay of therapy – patients with VLU should understand it will be needed *constantly and forever*. Compression cannot be used when the patient has significant peripheral artery disease (ABI <0.7 or >1.2). A toe–brachial index >0.6 or a transcutaneous oxygen measurement >30 mmHg indicates adequate arterial flow to use compression therapy.
 - a. Graduated pressure compression stockings should be worn daily when the patient does not have a VLU.
 - b. 4-layer compression wraps changed weekly can be used when VLU is present. A long-lasting topical antimicrobial dressing can be placed on the ulcer beneath the compression wrap if the VLU is infected.

- c. Intermittent pneumatic compression stockings can be used by persons who cannot wear compression stockings.
2. Elevate extremity – keep affected legs elevated when possible and especially when not using compression, as edema limits oxygen diffusion to the tissues.
3. Increase calf muscle pump functions – targeted exercises can help.
4. Surgical interventions
 - a. To treat valvular incompetence – only effective when disease is limited to superficial venous system, should not be used when deep venous disease, DVT, or obstruction are present as it can make ulcers more recalcitrant
 - i. Subfascial endoscopic perforator surgery – procedure of choice
 - ii. Superficial venous ablation
 - iii. Endovenous laser ablation
 - iv. Valvuloplasty
 - b. Wound debridement – VLU are notorious for polymicrobial infection (suspected biofilm infection); routine weekly debridement is recommended to disrupt and help prevent biofilm infection²³¹
 - c. Tissue biopsy – ulcers present for longer than 3 months or which fail to respond to treatment after 4–6 weeks should be biopsied to evaluate for malignancy or other atypical causes of leg ulcers such as vasculitis, or cutaneous manifestations of systemic disease
 - d. Free tissue transfer – can provide durable treatment for large recalcitrant ulcers by improving venous hemodynamics and removing all lipodermatosclerosis-affected tissues that prevent ulcer healing.^{232,233}

Outcomes/prognosis/complications

1. Contact dermatitis – because of multiple prolonged exposures to topical agents
2. Soft tissue necrosis – when compression is applied to patients with concomitant arterial insufficiency
3. Malignancy – squamous cell and basal cell carcinomas are most common
4. Infection* – frequently polymicrobial, routine use of topical antimicrobial dressings is not recommended without a diagnosed wound infection
5. Deep venous thrombosis – stasis and inflammation are major contributing factors
6. Ulcer recurrence – approximately 50% of VLU recur within 10 years²³⁰

*Hints and tips – Hydrofera Blue® (Hollister, Inc.) is a foam dressing with gentian violet as the active antimicrobial agent. The foam dressing is absorbent, can be left in place under the compression wrap and gentian violet has broad antifungal and antibacterial activity (including MRSA and *Pseudomonas* spp.)²³⁴

Wound healing occurs as a well-coordinated series of biologic events. Clinical manifestations of dysregulated wound healing include: hypertrophic scars, keloids, and prominent granulation tissue, as examples of exuberant healing, while chronic wounds are stalled in the inflammatory phase. Every time a surgeon takes a scalpel to skin a wound is created. Understanding the fundamentals of wound healing will enable the surgeon to optimize conditions for good surgical outcomes. First and foremost attention should be paid to preparing the patient and the wound bed for healing or surgical coverage/closure.

Wound bed preparation

Patients with chronic open wounds typically have multiple comorbidities and these need to be medically optimized to ensure patients have the capacity to heal their wounds. Smoking cessation, adequate protein nutrition, and good glucose control as determined by hemoglobin A1c levels are essential. Patients with autoimmune or other inflammatory conditions need to have these controlled as well. For patients on chronic steroid therapy perioperative vitamin A

Fig. 13.20 Diabetic foot ulcer with multiple associated foot deformities including arch collapse, prominent metatarsal heads and claw deformity/hyperextension of toes.

Table 13.1 Medical comorbidities that impair wound healing

Malnutrition
Smoking
Renal failure
Radiation
Diabetes – poorly controlled
Heart failure
Hemoglobinopathies
Immunosuppression
Autoimmune inflammatory conditions – poorly controlled

supplementation may be beneficial to support wound epithelialization (Table 13.1).²³⁵

The physical examination of any wound, whether acute or chronic, must include palpation. Wounds should be probed for underlying fractures, retained foreign bodies, exposed hardware, communication with other joint spaces or body cavities and the presence of heterotopic bone when examining pressure ulcers. The presence of tunnels or undermining should be documented in the medical record. The periwound skin should be examined, looking for signs of additional injury such as induration, violaceous discoloration, redness, swelling, and signs of maceration including moist red skin with superficial ulceration (Fig. 13.22) and white rolled borders of the wound edge, called epibole (Fig. 13.23). One should look for the cardinal signs of infection (rubor, dolor, calor, tumor); and for chronic wounds pain has also been recognized as an indicator of potential underlying infection.^{236,237} However,

Fig. 13.21 Placement of absorbable antibiotic impregnated beads over debrided bone with known osteomyelitis

Fig. 13.22 Moisture-associated skin damage

Fig. 13.23 Epibole.

unless it is grossly apparent that the wound is infected, i.e., foul odor, purulent drainage with or without systemic manifestations of illness, then diagnosis of wound infection on the basis of clinical exam alone is unreliable.²³⁸ Biofilm infection of a wound suppresses the host inflammatory response, so physical signs of infection are not present. All of this information needs to be taken into consideration when performing debridement as part of the wound bed preparation.

Adequate debridement of wounds includes removal of all necrotic tissue and removal of epibole and periwound fibrotic tissue as these hyperproliferative cells do not migrate across the wound surface to promote closure.²³⁹ Unroofing areas of tunneling and undermining, specifically removing skin covering these areas even if the skin is healthy, needs to be done to provide adequate care of the wounds and facilitate planning of surgical coverage. Wound tissue biopsies for culture should be obtained once debridement is complete to determine whether bacteria remain in the wound. Sending the excised necrotic tissue for culture is not informative. Alternatives to sharp debridement include enzymatic debridement agents such as collagenase, mechanical debridement using wet to dry dressings, biodebridement using maggots, and non-contact low frequency ultrasound therapy (MIST® – Alliqua Biomedical).

Ensuring adequate wound bed perfusion and oxygenation is an absolute requirement for wound healing to occur. Oxygen is required for respiratory burst to kill bacteria, it is required for ATP production, cellular energetics, intracellular signaling and collagen synthesis. Elective debridement of wounds should not be performed until it has been established that there is adequate perfusion to support wound healing. For lower extremity wounds palpation of pedal pulses should always be the starting point. If pedal pulses are diminished non-invasive vascular studies such as ankle-brachial index, toe-brachial index, transcutaneous oxygen measurements, or imaging modalities that demonstrate blood flow such as laser speckle, or laser Doppler flowmetry can be used. For those patients who cannot be revascularized, have multiple comorbidities, and are immobile with no functional goals, dry stable eschar on the heels can be left intact.²⁴⁰ The term dry stable eschar denotes black eschar tightly adherent to the wound with no drainage, redness, or odor. These are essentially treated like dry gangrene that is allowed to auto-amputate as the wound bed below heals. The eschar should be debrided if signs of infection develop. Perfusion to wounds should be considered on an angiosomal basis, i.e., is the perforator vessel to the skin patent and is the source vessel for the perforator patent. If perfusion and oxygenation are poor due to source vessel obstruction or occlusion, then options for improving perfusion include peripheral vascular bypass or endovascular stenting. While permanent patency of stents is ideal, the objective is to have patency long enough to get wounds healed and eliminate the risk for limb loss. Reducing peripheral edema is also an important adjunct to improve tissue oxygenation as diffusion distance of molecular oxygen from capillaries is significantly decreased with tissue edema.

If pressure is a contributing etiologic factor then offloading measures need to be included to enable wound healing. For diabetic foot ulcers this would include modified footwear, total contact casting or non-weight bearing on the affected limb. For pressure injuries this would include the use of cushions to pad wheelchairs and protective boots to offload heels for patients who are bed bound.

Wound dressings

The selection of a wound dressing needs to be individualized to each patient. The ideal dressing according to the British National Health System is one that can absorb and contain exudate, does not leave particulate contaminants in the wound, provides thermal insulation, does not traumatize the wound bed when removed, is impermeable to water and bacteria, minimizes the frequency of dressing changes, and provides pain relief and comfort when used.²⁴¹ In general, inexpensive basic options for wound dressing should be tried first. If wounds fail to respond after wound bed preparation and use of first line therapies, then practitioners should progress to using advanced therapies. It should be noted that the Cochrane Database of Systematic Reviews has performed many meta-analyses on wound healing and states that there is no evidence to indicate the superiority of any type of wound dressing.^{241–243} A list of the different types of first line dressings and the indication for their use is included in Table 13.2.

Advanced therapies in wound healing

Growth factors

These are soluble factors that stimulate cells such as fibroblasts and keratinocytes via transmembrane glycoprotein receptors.²⁴⁴ Platelet-derived growth factor (PDGF) is most studied among the growth factors and a recombinant version (rhPDGF) showed positive effects in a randomized double blind study of DFUs.²⁴⁵ rhPDGF marketed as Regranex® (also called becaplermin) is the only FDA-approved growth factor product in the market specified for use in DFU treatment. This therapy has been shown to rely on ROS for biological functionality.²⁴⁶ It has also been shown to accelerate wound healing in irradiated wounds and abdominal wall separations.^{247,248} Another growth factor based product that is considered to be closer to the natural healing process is the autologous platelet gel (APG) treatment that is a composite of multiple growth factors derived from the patient's own blood. APG has been tested with chronic skin and soft tissue ulcers, burns, trauma surgery, etc., and has shown promise.^{249,250}

Extracellular matrix (ECM)

Acellular, collagen rich scaffolds derived from varied sources such as human or porcine dermis and porcine small intestinal submucosa (SIS) have been used for various procedures such as facial reconstruction and abdominal wall repair. AlloDerm® (human dermis), OASIS® (SIS) and MatriStem® (porcine bladder submucosa) have all been applied as treatments for different types of non-healing wounds (DFUs, VLU and PUs) and found to accelerate the process of wound healing.^{251–256} These ECM products are advantageous because they provide a scaffold containing collagen and additional growth factors such as TGF-β, VEGF and FGF, which combine to promote granulation and epithelialization of dermal wounds resulting in healing. There are also ECM products that do not contain bioactive growth factors, such as Prisma®, made of oxidized cellulose and collagen that has been shown to improve healing rates in diabetic foot ulcers in a small randomized controlled

Table 13.2 Common wound dressings

Dressing	Indications	Examples
Foam – hydrophilic polyurethane fibers absorb fluid	Light to medium exudate, comfort, protect against shear	Mepilex® (Mölnlycke)
Antibacterial – all the types of dressings listed here have antibacterial properties	Infected wounds	Manuka honey, silver, iodine, gentian violet, chlorhexidine, polyhexamethylene biguanide (PHMB), antibiotic ointments
Alginate – made from calcium alginate derived from seaweed, can absorb up to 20 times its weight in fluid	Highly exudative wounds – requires secondary dressing	Calcium alginate
Hydrogel – cross-linked gelatin or other insoluble fibers in solution with high water content	Hydration of desiccated wound bed to promote healing – requires secondary dressing	Duoderm® gel (Convatec)
Hydrocolloid – gelatin, pectin or carboxymethylcellulose bonded to stiff backing that is impermeable to water and bacteria	Superficial wound with minimal exudate and no tunnels or undermining, promotes autolytic debridement	Duoderm® (Convatec)
Hydrofiber – soft absorbent material that turns into a gel on contact with wound	Use to manage low to moderate exudate	Aquacel® (Convatec)
Charcoal infused	Odor management	Fungating tumors, foul-smelling wounds
Barrier creams	Protect periwound skin from maceration or fecal/urine contamination	Zinc oxide, Aloe Vesta® protective ointment (Convatec)
Protease modulating matrix – collagen substrate for the proteolytic enzymes present in wounds to protect wound bed from enzymatic degradation	Chronic wounds, moderate exudate	Promogran™, Promogran Prisma® (Acelity), Puracol® (Medline), Endoform™ (Hollister)

trial.²⁵⁷ Patients that responded well to the Prisma® product had decreased levels of MMP-9 and elastase at the wound site suggesting that the dressing may provide a substrate for enzymatic digestion to prevent soft tissue at the wound site from being targeted and limiting inflammation.

Engineered skin

Since the 1980s, the use of engineered biologic material for chronic wound therapy has evolved to expedite wound healing by providing scaffolds and release of growth factors to support cellular growth and re-epithelialization. Epidermal autografts were the first to show promise but had drawbacks related to the lack of a dermal component that have limited their applications. Apligraf®, a bilayered skin equivalent derived from neonatal foreskin and grown on bovine collagen matrix, showed promise in phase III clinical trials for chronic wounds such as venous ulcer and DFU and is now FDA approved for therapeutic use in the context of these ulcers.^{258,259} However, the allogeneic origin of the cells, growth on bovine collagen and lack of dermal structures such as hair follicles and sweat glands add a cautionary note on wide applicability. Dermalgraft® is a cryopreserved, three-dimensional human dermal substitute composed of human fibroblasts in a dissolvable mesh with an FDA approval for use in DFUs.²⁶⁰ It has also shown promise in other applications such as VLU and PU.²⁶⁰ Integra™ is a partial biologic dressing composed of a bovine collagen matrix and a glycosaminoglycan from shark cartilage associated with a temporary silicone epidermal sheet.^{260,261} This is indicated for use in partial or full thickness burn wounds and non-burn wounds such as VLUs, PUs and traumatic soft tissue reconstruction over exposed joints and bone.^{262,263}

Oxygen therapy

Hypoxia is a double-edged sword in wound healing and exists in wounds as a gradient from the center (most hypoxic) to the periphery (least hypoxic). While hypoxia plays a role in initiation of neovascularization upon acute exposure, chronic hypoxia is known to impair angiogenesis.^{264,265} Therefore the application of oxygen therapy to promote wound healing has value and indeed applied systemic hyperoxia (hyperbaric oxygen therapy (HBOT)) has been shown to effectively treat necrotizing infections, and increase angiogenesis, granulation tissue formation, wound contraction and secondary closure. There are currently 15 CMS-approved indications for HBOT treatment (www.cms.gov). This involves enclosing the patient in a special chamber where 100% oxygen at 2–3 atmospheres of pressure is applied for 60–120 minutes. The treatment is given 5 days a week for about 10–60 treatments depending upon the type of wound being treated. This results in saturation of oxygen-carrying capacity of hemoglobin and high levels of dissolved oxygen carried in the plasma. Dissolved oxygen in the plasma diffuses across the capillary bed in response to tissue oxygen gradients. This is a highly specialized treatment modality delivered by physicians and staff that have had additional training in hyperbaric medicine and administration of HBO therapy. There are some risks associated with this treatment including middle ear barotrauma with perforation of the tympanic membrane, seizures, hypoglycemia, and exacerbation of heart failure. However, the benefits of HBO are significant. A meta-analysis on HBO therapy for diabetic foot ulcers found that for every 4 patients that received HBO it prevented 1 major, i.e., below knee or higher level, amputation.²²⁴

Topical oxygen (TO) therapy involves the local application of 100% O₂ at slightly above 1 atmosphere pressure for 90 minutes once a day for 4 consecutive days followed by 3 days of no treatment. It has been shown to oxygenate superficial wound tissue up to 2 mm deep²⁶⁶ in the optimal therapeutic range (40–80 mmHg) that enhanced VEGF expression (unlike HBOT)²⁶⁷ and angiogenesis in human wounds. This treatment is typically given to patients in their home. Guidelines for the selection of patients and application of TO therapy for optimal use have been defined and suggest that this therapy could be considered for treatment of refractory wounds.²⁶⁸

Negative pressure wound therapy

Negative pressure wound therapy (NPWT) is a well-known treatment modality used to promote healing in acute or chronic wounds. The basic concept of NPWT involves the use of a moistened foam or antimicrobial gauze dressing, covered with a transparent adhesive cover, attached to a vacuum pump that creates a sub-atmospheric pressure environment to the wound area. The intrinsic mechanotransductive properties of the skin are modulated for beneficial effects with the use of this therapeutic modality.²⁶⁹ The extrinsic tensile forces being applied to the wound surfaces are proposed to (a) cause shrinkage of wound area because of mechanical contraction, (b) apply a microstrain that alters the shape and function of individual cells, (c) remove fluids and reduce edema thereby inducing a return to osmotic homeostasis and (d) maintain a moist and stable wound environment which is conducive to healing.^{269,270} This therapy can be adapted to meet individual patient needs in combination with other therapies (antimicrobial silver, skin substitutes such as Apligraf® and Integra™ and a wireless electroceutical dressing)^{270–273} and has been indicated to be useful in the case of DFU and VLU.^{274,275} However, a serious complication associated with this treatment is bleeding and therefore it should not be placed directly over areas of vascular repair or anastomosis.²⁷⁶

Electroceuticals

An intrinsic electric field and natural direct currents are present in the skin and are essential for normal regeneration in lower vertebrates, and their reversal induces degeneration. The human skin maintains an intrinsic transepithelial potential (TEP) in the intact skin. When the skin is wounded, the potential difference between the wound and the surrounding intact skin generates an endogenous electric field (10–100 μA/cm²) around and directed into the site of the wound and the cells within this field respond to the presence of this field.^{277–282} Electrostimulation (ES) therapy is based on the premise that

an externally applied electric field can then result in an electric current being driven along the wound surface, enhancing the endogenous electric field and aiding the healing processes. This field has been shown to promote several major signaling cascades that influence the directed migration of numerous cells (such as keratinocytes, fibroblasts, endothelial cells and immune cells) that are integral to the wound healing response.²⁸³ Although the concept of ES therapy has existed for over a hundred years, it has primarily impacted neuronal stimulation (cochlear implants, spinal cord, deep brain stimulation) and cardiac function (pacemakers) and there are FDA approvals for many of these applications.^{284,285} The use of ES for wound care applications has been slowly gaining momentum. Several clinical trials have addressed the application of various types of electrical stimulation such as direct current (DC), alternating current (AC), high-voltage pulsed current (HVPC) and low-intensity direct current (LIDC) for all types of chronic wounds.^{285,286} However, some limitations include ease of application of these treatments and variations in efficacy of the different ES treatments because of lack of standardized parameters (voltage, type of current (direct vs alternating), mode and length of time for treatment) for use. In 2002, Centers for Medicaid/Medicare Services approved reimbursement of ES treatments of chronic ulcers that did not respond to standard therapies.²⁸⁷ The FDA has not yet approved ES applications for wound care with the exception of a woven bandage with embedded microbatteries that acts as a wireless electroceutical dressing (WED).²⁸⁸ Microcell batteries of silver and zinc, activated by a moist environment, generate an electric field of 0.1–1 V which stimulate wound healing and provide antimicrobial protection (Procellera™, Vomar Innovations). The molecular mechanisms involved in the enhancement of wound healing by ES have been studied *in vitro*. Electric fields generated by this dressing improved keratinocyte migration via redox-dependent processes²⁸⁹ and disrupted bacterial biofilm by repressing quorum sensing and redox-sensitive multidrug efflux pathways.²⁹⁰ This novel electroceutical dressing, used in conjunction with NPWT in a randomized clinical trial, decreased the frequency of dressing change and lowered the cost of the associated wound care.²⁷³

Scar prevention, treatment, and revision

Michael S. Hu, Elizabeth R. Zielins, Michael T. Longaker, and H. Peter Lorenz

SYNOPSIS

- Preventing and treating problem scars are vital to patient satisfaction and good outcomes in all surgical cases, ranging from the most precise aesthetic work to the most challenging reconstructive procedures. Understanding how scarring occurs helps to structure our surgical planning, approach, and technique. In follow-up care, minimizing scarring can lead to improved form and function as well as increased patient satisfaction. Even long after recovery, patients with pathologic or abnormal scarring may seek the expertise of a plastic surgeon for scar revision. However, even the most experienced surgeons can attest to the challenges of managing scar tissue in reoperative surgery.
- To begin to tackle such obstacles, plastic surgeons have created an arsenal of tools based on the central tenets of our discipline. Published in 1957 by Gillies and Millard, *The Principles and Art of Plastic Surgery* set out fundamental doctrines of plastic surgery and defined the foundational knowledge of our field.¹ Operative scar treatment and revision procedures rely heavily on these principles. Ideas such as diagnosing before treating, making a plan, marking landmarks, “borrowing” tissue from other areas, and restoring the beautiful normal represent our approach to the management of scars. Instead of having a specific operation for each defect, the plastic surgeon is charged with using these principles to optimize therapeutic options for each individual patient.
- To the surgical armamentarium we continue to add our growing understanding of scar biology. Fetal models have shed light on the complex factors that determine scarring versus scarless wound healing. In addition, we have deepened our understanding of the mechanisms that lead to pathological hypertrophic and keloid scar formation. Such advances in cell and tissue biology have revealed many new therapeutic targets, which are currently under active investigation.
- Each treatment plan begins with the patient. A good treatment outcome is rarely achieved without first understanding the patient’s antecedent experience, current complaints, and future expectations. Here we will describe important aspects in approaching a scarred patient, assessing a scar and understanding scar biology. We will then focus on strategies for preventing, treating, and revising scars. These

strategies are defined by both modern advancements in medicine as well as time-proven principles of surgery.

Personal and social significance of scars

For physicians, scars represent an endpoint in wound healing. For patients, however, scars exemplify something far more deeply personal and emotional. Scars caused by disease, violent trauma, or aberrations of development can result in lifelong physical and psychological burdens. Treating scars thus requires an understanding of the psychological and social distress a patient may experience.

Scars may arise from both culturally sanctioned and prohibited practices. Ritual scarring, or cicatrization, was an important part of identifying tribal belonging in parts of Africa and Australia.² In tribal communities in Sudan and Papua New Guinea, the prevalence of keloid formation in certain racial groups was exploited for spiritual and cultural markings. Likewise, the Japanese art of tattoo, or *irezumi*, carried sufficient cultural weight as to be banned by the Meiji government until 1945, when occupational forces again legalized its practice. Today tattooing and, to a lesser degree, branding and scarification, continue to be a popular form of self-expression.³

Gender plays a clear role in the effect of scars in society. A recent study suggested that facial scars in men indicate risk-taking and bravery, and these men are subsequently perceived as more attractive.⁴ The same effect was not found when observers were shown similarly scarred women. Nevertheless, many scars carry negative social implications for both genders. Studies of quality of life measures in burn patients reveal that scars cause significant decrease in the quality of patients’ social and professional life.⁵ For instance, both depression and post-traumatic stress disorder (PTSD) have been identified as potential long-term sequelae, with rates for PTSD in burn patients ranging from 23% to 45% at 1 year

following injury.⁶ Risk factors include avoidant coping strategies and pre-existing psychiatric history, as well as hand and face involvement and burn severity.⁷ Therefore understanding the specific aspects of the patient's life most affected by the presence of scarring can help direct both medical and non-medical therapy.

Psychologist Thomas F. Cash described the importance in reconciling a patient's "view from the outside" and "view from the inside" when coping with deformity.⁸ Understanding the social context and patient's emotional relationship to scars is vital to treatment. A potentially useful tool in understanding and assessing these variables is *Psychological Aspects of Reconstructive and Cosmetic Plastic Surgery: Clinical, Empirical, and Ethical Perspectives*.⁹ This title reflects a multidisciplinary effort of leading psychologists, psychiatrists, and surgeons in determining and delivering care to patients with real or perceived deformities.

History and physical examination

As with the evaluation of most maladies, assessment of a patient with an unsatisfactory scar begins with a focused history and targeted physical examination (Box 14.1). While obtaining the history, the etiology of the scar and relevant associated factors (e.g. prior dissatisfactory surgery, relation to violent crime or infection) should be elucidated. In communicating with the patient, the treating physician should be empathetic without attempting to attribute the patient's current complaints to care provided by prior treating physicians. This can usually be accomplished by focusing on the problem at hand and appropriate next steps.

The physical exam includes an assessment of both the scar and surrounding tissue. With facial scars, attention must be paid to normal folds and features as determined by the aesthetic subunits.¹⁰ Examination of other scars on the patient to determine predisposition to poor scarring can also be helpful. Evaluation of the scar should include written and photographic documentation of size, color, and texture. The relationship of the scar to surrounding structures in motion and repose should be carefully assessed to determine tethering and contracture.

Scar formation can cause functional, aesthetic, and emotional problems. Before initiating treatment, the physician

must take the time to understand and address each of these elements. The extent of scar should be considered along with the patient's goals in getting treatment. Arriving at realistic targets and expectations may require multiple visits or a combination of surgery and counseling. Frequently, scheduling a second or third visit to ensure the patient understands the treatment plan and has realistic expectations prior to undergoing the planned procedure is in the surgeon's best interest.

Assessing scars

Clinical evaluation of a scar is necessary in determining the best course of treatment and effectiveness of therapy. The ideal scale for scar assessment should demonstrate validity, inter-observer reliability, and clinical applicability. Though multiple objective and subjective assessment tools have been devised to characterize scars, there is as yet no universal consensus on scar grading. However, the most frequently used measure is the Burn Scar Index, also known as the Vancouver Scar Scale (VSS) (Table 14.1).¹¹ Originally published in 1990, the VSS is an observer-dependent scale designed to assess changes in burn scars with maturity and in response to

treatment. Scars are assessed based on four variables: pigmentation, vascularity, pliability, and height. Scores are then assigned across these four variables based on the degree of variance from normal skin. When applied, the scale can be a useful tool for prognosis and treatment evaluation. In 1995, Baryza and Baryza¹² found that adding a low-cost instrument could improve inter-observer reliability. They combined a ruler, a transparent piece of plastic, and a scoring “cheat sheet” to aid in measuring, blanching, and determining the score, respectively.

While perhaps the most commonly used assessment tool, the VSS is limited by its historical focus on burn scars, lack of consideration of patient’s own perceptions, exclusion of pain and pruritus, as well as a lesser applicability to larger scale heterogeneous scars.¹³ Other evaluation measures, such as the Visual Analog Scale (VAS), the Patient and Observer Scar Assessment Scale (POSAS), the Stony Brook Scar Evaluation Scale (SBSES), and the MCFONTZL classification system have been created with varying levels of validation and adoption.¹⁴ The large variety of different scales reflects the relative imperfection of each individual system.

The VAS assesses parameters such as color, contour, and texture to correlate intra-observer as well as photographic and histologic findings.¹⁵ The scale can be applied to both burn and surgical scars. Similarly, the POSAS was developed in 2004 for burns and has since been validated for linear scars. This scale has the benefit of incorporating patient opinion to a VSS-like scale and can better assess symptoms such as pain, itchiness, and thickness.^{16,17} A third scale, the SBSES, is a photo-based scale similar to VAS and was initially developed as a tool for emergency medicine physicians to evaluate wounds from 5 to 10 days after wounding up to the time of suture removal.¹⁸ The SBSES has since been adapted for long-term evaluation of scars 3 to 12 months after injury and has been used as an outcome measure in Food and Drug Administration-mandated clinical trials.¹⁹ Lastly, the MCFONTZL classification system was developed specifically for facial trauma (Table 14.2).²⁰ This system incorporates billing and uses a mnemonic to divide the face into the maxilla, chin, forehead, orbits, nose, temple, zygoma, and lip. These scales have been useful in comparing outcomes from conventional versus minimally invasive surgery, use of wound

closure adhesives, and new therapeutic agents for scar treatment.

A number of instruments have also been used to facilitate objective assessment of scars. Blood flow has been analyzed by laser Doppler, while depth and color have been studied by ultrasound and spectrometry.²¹ Skin elasticity meters, commercialized for evaluation of scleroderma, have also been used to examine scars.²² Lastly, three-dimensional systems have been used in a number of studies to create high definition and easily reproducible topographic representation of scars. While these instruments demonstrate a high degree of accuracy, reliability and clinical utility, the added expense and additional technical training required have limited them largely to research settings.

Scar biology

Scar formation is a physiologic response to injured tissue and reflects the body’s attempt to restore tissue strength and integrity. The imperfect nature of this process likely reflects a trade-off of organization for debridement and sterilization, and results in distinct morphologic differences between scarred and normal tissue. A mature scar, the final product of normal wound healing, is characterized by a disorganized array of collagen and loss of dermal appendages. However, scars are not static entities. Instead, scar formation is a dynamic process, beginning at the initial injury and proceeding temporally through the phases of wound healing to produce a mature scar (Fig. 14.1).

Normal wound healing is a complex process that can be roughly divided into three overlapping stages: inflammation, proliferative matrix formation, and remodeling. Inflammation, the first stage of wound repair, is characterized by infiltration of immune cells attracted by various cytokines, invading pathogens and growth factors towards the wound site. Platelets also aggregate at the site of injury, resulting in activation of the coagulation cascade and leading to the formation of a fibrin clot.²³ This initial cellular response is aimed at the establishment phagocytosis of injured cells and hemostasis. In a non-infected wound, inflammatory cells are then replaced by fibroblasts in the proliferative stage of wound healing. This phase is characterized by synthesis and secretion of the extracellular matrix (ECM).

ECM is formed through a highly regulated process of synthesis, deposition, and degradation by fibroblasts that migrate to the wound in response to TGF- β , PDGF and other growth factors. The initial wound environment is largely composed of fibrin and the glycosaminoglycan hyaluronic acid. As fibroblasts populate the wound, enzymes degrade the matrix and collagen is deposited. Cross-linking and organization of the collagen ultimately create tensile strength across the wound. The process of collagen deposition and degradation is in part determined by the regulation of matrix metalloproteinases (MMPs), which in turn, are inactivated by proteins called tissue inhibitors of metalloproteinases (TIMPs). The balance of MMP-TIMP function remains an active area of research in wound healing and scar biology.²⁴

At the cellular level, scars are characterized by a lack of connective tissue organization compared to surrounding normal tissue architecture. Grossly, the early or immature scar is red because of its dense capillary network. Over a period

Table 14.2 MCFONTZL assessment system

A area	MCFONTZL aesthetic unit designation
S Side	
T Thickness	Depth of penetration
E Extension	Branching
R Relaxed skin tension line conformity	Directionality (relaxed skin tension lines)
I Index laceration	Laceration with maximum continuous skin interruption

of months, the capillaries regress until relatively few remain and the red color fades. The scar remodels slowly over months to years to form a “mature” scar. Mature scars are usually hypopigmented and appear lighter than the surrounding skin. However, they can occasionally be hyperpigmented and darker than the surrounding skin. Hyperpigmentation is more common in darkly pigmented patients or lighter-pigmented patients whose scars receive excess sun exposure. For this reason, surgeons recommend sun protection for patients with early scars on sun-exposed areas such as the scalp, face, and neck.

During the remodeling phase, wounds gradually become stronger with time. Wound tensile strength increases rapidly from 1 to 8 weeks following initial injury. Thereafter, tensile strength continues to increase, albeit at a slower pace, and has been documented to continue to increase up to 1 year in

animal studies (Fig. 14.2). Nevertheless, the tensile strength of wounded skin only reaches approximately 80% of the tensile strength of unwounded skin at best. A mature scar, the final result of tissue repair, is brittle, inelastic, and without skin appendages such as hair follicles or sweat glands. The cost of these imperfections is counterbalanced by the benefits of rapid re-establishment of tissue integrity, debridement, and sterilization of contaminated wounds.

Conditions of excessive scarring

Wound healing is a tightly regulated process involving cell–cell signaling and environmental cues. In normal wounds, repair slows when the dermal defect is closed and epithelialization is complete. But when appropriate signals are absent

Fig. 14.2 Wound tensile strength with time. Wounds reach approximately 80% of their preinjury tensile strength at 6 weeks. Further gains occur slowly over time and never achieve 100% preinjury strength.

or ineffective, the repair process may continue unabated and result in surplus scarring. Hypertrophic scars and keloids, both fibroproliferative disorders of wound repair, are two examples of this.

In general, both keloid and hypertrophic scar fibroblasts have an upregulation of collagen synthesis, deposition, and accumulation. However, the underlying regulatory mechanisms responsible for this excessive repair are still under investigation. Both profibrotic cytokines such as transforming growth factor- β 1 (TGF- β 1) as well as a lack of programmed cell death, or apoptosis, of activated fibroblasts secreting ECM components have been implicated in excessive scarring.^{25,26} For unknown reasons, hypertrophic scars and keloids are unique to humans and do not naturally occur in other animals.

Normotrophic, hypertrophic, and keloid scars vary little histologically.²⁷ Pathological scar types are therefore distinguished based on clinical characteristics. Hypertrophic scars continue to thicken and rise instead of flattening and shrinking like mature scars, but stay within the original scar boundary. In contrast, keloid scars grow beyond the boundaries of the initial wound (Table 14.3). Because the timeline from immature to mature to hypertrophic and keloid scar formation can vary due to a number of factors, diagnosis is not always clear. Clinical monitoring of scar evolution with frequent serial examinations is the most important strategy for diagnosing

Fig. 14.3 (A,B) Hypertrophic scars.

and treating the problem scar. Early application of treatment modalities, discussed in depth later in this chapter, can often prevent further progression and even reverse scar pathology.

Hypertrophic scar

Hypertrophic scars are defined as pathologic scars that have not overgrown the original wound boundaries, but are instead abnormally thickened and raised (Fig. 14.3). Hypertrophic scars are often painful and pruritic. This is thought to be due to release of proinflammatory neuropeptide substance P from nerve endings following injury.²⁸ Hypertrophic scars usually

Table 14.3 Types of scar			
	Appearance	Growth pattern	Cause
Normal mature scar	Hypo- or hyperpigmented, flat	Contracts slowly over time	Normal tissue repair
Immature scar	Red, slightly elevated, sometimes itchy	Turns into mature scar	Normal tissue repair
Hypertrophic	Raised, itchy, painful, confined to its borders	Self-limited, but may take years	Excess mechanical stress
Keloid	Raised, itchy, extending into normal tissue	Continued growth; recurs	Genetic predisposition; can result from minor trauma

form secondary to excessive tensile forces across the wound and are most common in wounds across flexion surfaces, the extremities, breasts, sternum, and neck.

Hypertrophic scarring is a self-limited process and usually regresses with time. These scars eventually fade in color and flatten to the surrounding skin level, though the unaided process may take years. No clear histological differences between hypertrophic scars and keloids exist. Early studies found that keloids contained bundles of collagen around focal nodules of proliferation.²⁹ Later studies, however, refuted this distinction.

To date, clinical treatment of hypertrophic scars remains unsatisfactory, and is reflective of our incomplete understanding of mechanisms underlying hypertrophic scar formation. The creation of consistent and reproducible models for testing new treatment modalities, particularly animal models of hypertrophic scars, is key to advancing our knowledge of hypertrophic scar biology.^{30,31}

Keloid

Scars that overgrow the original wound edges are called keloids (Fig. 14.4). This clinical characteristic distinguishes

keloids from hypertrophic scars. True keloid scars are not common and occur predominantly in darkly pigmented individuals, with an incidence of 6–16% in African populations. This demonstrates genetic predisposition with autosomal-dominant features. The keloid scar behaves like a benign skin tumor with continued slow growth, and in the majority of cases complete excision with primary closure of the defect results in recurrence.

Keloids consist primarily of collagen. They are relatively acellular in their central portions with fibroblasts present along their enlarging borders. Keloids do not, however, contain a significantly elevated number of fibroblasts. Rather it appears that collagen deposition outpaces degradation, allowing the lesion to enlarge.

Keloid formation may be the result of excessive stimulation or an inappropriate response to stimulation. *In vitro* studies find that keloid keratinocytes and fibroblasts respond differently to growth factors found at the repair site. TGF- β treatment, for example, causes a greater degree of collagen gene expression in keloid compared to normal wound fibroblasts.³² In addition, a greater degree of profibrotic growth factor expression occurs in keloids compared to normal wounds.³³ Together, these and other studies suggest that keloid

Fig. 14.4 (A–D) Keloids. (With permission from Dr. Shelly Noland.)

formation occurs because of increased expression and activity of proliferative growth factors at the wound site.

Alternatively, a defect affecting the repair process may result in the absence of appropriate “stop” signals for healing. In this proposed mechanism, a lack of stop signals in the wound results in continued and unchecked repair. Studies of apoptotic cell numbers have found similar amounts of apoptotic cells at the advancing wound edge in both normal and hypertrophic scars. In keloid scars, however, decreased expression of apoptotic genes was found.³⁴ The biology of keloids continues to raise important questions about what factors govern normal and pathologic healing.

Prevention

Surgical technique

The molecular regulation of scar formation aside, meticulous surgical technique continues to be the cornerstone of successful scar minimization (Box 14.2). To begin, the plastic surgical craft utilizes fine instruments and atraumatic technique to minimize trauma to tissue. For example, hooks for retraction and avoidance of double grasping with forceps help prevent crush injury to delicate tissue.

Obtaining a fine pencil-line scar also relies on relieving tension on the apposed epidermal edges (Fig. 14.5). Undue tension clearly plays a role in widened and hypertrophic scars. Wound tension causes edge separation and scar widening with time. Wound edges that are sharply defined and aligned without tension heal with the least amount of scarring. This is accomplished by approximating tissue with deep buried subdermal stitches to minimize tension of overlying tissue before final apposition. Additionally, the Gillies near-far pulley can be used to aid approximation of higher tension tissue. Skin eversion can be seen as an exaggerated application of the principle of tension-free closure and can be accomplished with horizontal mattress and “flask-shaped” simple sutures. However, care must be taken not to strangulate tissue with overly tight stitches.

To prevent Burrow’s triangles (“dog ears”), sutures should be placed at the wound periphery so that redundancy can be worked towards the middle, allowing for cleaner alignment along the epidermis of the two wound edges during apposition. When tissues of differing thicknesses are closed, care should be taken to capture a deeper bite of the thinner tissue and a more superficial bite of the thicker tissue for proper alignment. Likewise, when tissues are at differing heights, taking a deeper bite of the lower tissue can help bring that tissue level.

BOX 14.2 Surgical technique

- Atraumatic technique
- Minimizing tension
- Skin eversion
- Perfect apposition
- Use of natural skin tension

Final closure can be achieved through fine interrupted and mattress stitches if care is taken for prompt suture removal. Removing sutures on the face should be performed no later than 3 to 5 days after placement. If necessary, the wound can be reinforced with adhesive tape strips at the time of suture removal. Failure to remove stitches in a timely fashion can result in a disfiguring railroad scar pattern from stitch marks.

Alternatively, subcuticular stitches or adhesive tissue glue can be used for final skin apposition. Permanent sutures such as polypropylene (e.g., Prolene®, Ethicon) or nylon incite less of an inflammatory reaction than absorbable biodegradable sutures. However, both permanent and absorbable subcuticular stitches can be left untied with the ends secured by tape to avoid granuloma formation around knots. Removal of permanent subcuticular suture can be aided by interval externalization of the stitch so the entire stitch does not have to be pulled through the wound.

To minimize visible scarring, elective incisions are least noticeable when placed parallel to the natural lines of skin tension (Langer’s lines) (Fig. 14.6). This placement location has two advantages: the scar is parallel or within a natural skin crease, which camouflages the scar, and the location places the least amount of tension on the wound.

Patient-specific factors

Factors that contribute to poor wound healing can also contribute to poor scarring. Poor nutrition, diabetes, obesity, and radiation exposure impair healing, and lead to an increased risk of infection. Patients with these comorbidities are at higher risk for wound complications and poor scarring. Medications such as corticosteroids and isotretinoin can also negatively affect tissue healing. Lastly, though the exact mechanism has yet to be determined, genetics plays a role in scarring, as demonstrated most dramatically in keloid formation.

Wound infections and foreign-body reactions

Wound infections and foreign-body reactions can lead to wound dehiscence and poor scarring. Increased proinflammatory cytokines may trigger abnormal fibroblast responses.³⁵ Leaving the initial dressing on for 48–72 hours, the time needed for epidermal closure, is a frequently used strategy to maintain wound sterility. Efforts to prevent wound infection, including debridement of any devitalized tissue and administration of perioperative antibiotics when indicated, should be a priority.

Adjunct therapy

As previously discussed, minimizing tension has been linked to decreased scarring.³⁶ Recently, a silicone elastomeric dressing that mechanically off-loads tension has been shown in two prospective, randomized controlled clinical trials to reduce scarring after scar revision surgery and abdominoplasty (Fig. 14.7).^{37,38} The device was applied 1–13 days following closure of an incision and applied weekly for 12–13 weeks. This tension off-loading device is a powerful new technology that represents the first and only level I evidence for scar reduction. Ongoing research may further demonstrate the effectiveness of this therapy for hypertrophic scars and keloids.

Fig. 14.5 (A–E) Skin eversion technique. Application of deep stitches approximates the dermis and relieves tension on the epidermis, contributing to less scar widening.

Fig. 14.6 Langer's lines.

Taping and coaptive films have also been used as adjunctive therapy to prevent abnormal scarring.^{39,40} Silicone gel sheeting, discussed in more detail later, has been considered first-line prophylaxis although evidence is weak. Treatment begins shortly after wound epithelialization, is worn 12–24 hours per day and continued for at least 1 month. Breast and abdominal binders work as external splints to decrease skin tension further. As with internal sutures, care should be taken not to constrict adequate blood flow to the wound edge. Current recommendations encourage the prophylactic use of these measures in patients who have wounds in high-risk areas such as the breast and thorax, or who have previously developed abnormal scarring.⁴¹

Studies of over-the-counter remedies such as vitamin E and onion extract have failed to provide good evidence in support of their use.^{42–44} These studies have been criticized, however, for their small sample size.⁴⁵ Modalities such as massage, hydrotherapy, and ultrasound also need additional investigation before their role in treatment of scars can be determined.

Lastly camouflage techniques can be a useful adjunct in addressing the psychosocial dimension of scar management. These strategies can be incorporated as a nurse-led aspect of a practice and may positively affect patient quality of life.^{46,47} A new spray-on, computer color-matched camouflage, Microskin, has been shown to improve psychosocial measures in pediatric burn patients.⁴⁸ The product is purported to be water- and sweat-proof, requiring reapplication every 4 to 5 days.

Treatment

Plastic surgeons today must apply surgical, nonsurgical, and multimodal strategies in treating disfiguring and pathologic scars. Treatment should be guided by diagnoses. Proper diagnosis requires addressing the patient's complaint, assessing the characteristics of the scar, and understanding the state of the scar with respect to scar biology. For instance, the approach to a 17-year-old male emotionally burdened by mature acne scars involving multiple facial subunits may require a combination of counseling and nonsurgical modalities. Alternatively, the functional impairment experienced by a 45-year-old woman with hypertrophic scar limiting elbow range of motion may require more invasive intervention. In general, noninvasive strategies as described below offer a good starting point in the treatment algorithm.

Fig. 14.7 Tension off-loading dressing.

Treatment of hypertrophic scar

Treatment options for hypertrophic scars include the application of pressure garments, silicone sheets, corticosteroids, laser therapy, and re-excision with primary closure. Primary closure is most useful in cases of excess scarring caused by infection or dehiscence. If the original wound was closed following the basic tenets described above, then re-excision with primary closure is not likely to result in an improved scar compared to the initial procedure. Recurrence of hypertrophic scarring is quite high in these circumstances. Most surgeons, therefore, do not treat hypertrophic scars with excision and primary closure unless adjuvant therapy is also planned.

Silicone gel sheeting can both prevent hypertrophic scar formation and accelerate its involution. Though a 2006 Cochrane review found only weak evidence to support silicone sheeting, multiple randomized control trials (RCTs) have since reconfirmed its value.⁴⁹ Silicone gel sheeting has demonstrated the ability to dramatically hasten hypertrophic scar maturation and decrease associated symptoms of pain, rigidity, and pruritus.^{50,51} However, silicone-containing oils and creams have also exhibited mixed efficacy and silicone's mechanism of action in treating hypertrophic scars is still under debate.⁵² One line of evidence points to increased hydration from occlusion with subsequent decrease in inflammatory cytokines.^{53,54} Alternative suggested mechanisms include a direct effect by silicone particles and an increase in static electrical fields.^{55,56} Studies of related polyurethane- and glycerin-based occlusive dressings are mixed, with some studies demonstrating effectiveness equal to silicone.^{57,58}

Since adoption in the 1970s, the use of compression garments has been a mainstay of burn scar management. Evidence in the literature, however, has been less clear-cut. A prospective RCT of 122 burn patients by Chang *et al.* failed to show significant improvement in time to scar maturation.⁵⁹ Conversely a subsequent, more precise RCT in 2005 by Van den Kerckhove *et al.* using both subjective and objective measures found improved scar thickness when garment pressure was above 15 mmHg.⁶⁰ Yet another study, a 2009 meta-analysis of six RCTs, including those mentioned above, found only marginal improvements of questionable clinical significance in scar thickness.⁶¹ To date various clinical studies are ongoing and the utility of compression garments in treating hypertrophic scars remain under debate.

Intralesional corticosteroid injections offer a second line of therapy for hypertrophic scars refractory to silicone gel sheeting. The exact mechanism is also unknown but likely reflects focal suppression of inflammatory cytokines and inhibition of fibroblast proliferation.⁶² Despite widespread consensus on its efficacy, few studies have objectively evaluated intralesional steroid treatment. The few studies that do exist suggest response rates well over 50%. However, these studies are limited by small sample sizes and unclear evaluation criteria.^{63,64} In one such study, multimodality therapy combining steroid injections with surgery improved response rates to 95% with no recurrence of scarring.⁶⁵ However local side effects from steroid injection include pain, skin atrophy, telangiectasias, and dyspigmentation, demanding careful application.

Pulsed-dye laser and other wavelength-specific lasers have been used effectively to treat hypertrophic scars for many

years. Though the mechanism of action is unknown, one hypothesis suggests that laser absorption by hemoglobin results in capillary ablation and reduced perfusion. The heat generated may also cause dissociation of disulfide bonds with collagen fiber realignment.⁶⁶ However, definitive conclusions have been hampered by small sample size, short-term follow-up, and lack of adequate controls. Review of the dermatologic literature suggests some efficacy when lasers are used as a monotherapy, especially in symptomatic relief of pruritic and erythematous lesions.⁶⁷ While ablative CO₂ and argon lasers have fallen out of favor in treating proliferative scars due to high recurrence rates, newer high-energy pulsed CO₂ and Er:YAG lasers are under investigation and show promise in the treatment of atrophic scars.⁶⁸ Larger-scale studies with long-term results are needed to further delineate the role of laser therapy in scar management.

Topical treatments for hypertrophic scars offer the advantage of convenience. Unfortunately, an effective topical therapy has not yet been developed. Over-the-counter remedies, including vitamin A, vitamin E, and onion extract, have failed to show conclusive evidence in treating or preventing hypertrophic scarring. A prescription topical immunomodulator, imiquimod 5%, has also been investigated for scar treatment and prevention. While early results suggested improved cosmesis in postsurgical scars, subsequent studies have failed to reproduce these effects.^{69,70} Skin-lightening agents containing hydroquinone or retinol can aid in the treatment of hyperpigmented scars.⁷¹ However their use is associated with significant side effects. For instance, in 2006 concern over the carcinogenic risk of hydroquinone prompted a ban of over-the-counter preparations over 2% in the US and a comprehensive ban in Europe.

Treatment of keloid scar

There exists no uniformly successful treatment for keloid scars. Therefore it is essential to discuss the risk of recurrence with potential patients prior to embarking on therapy. Nevertheless, patients frequently seek treatment due to the disfiguring physical and psychological burden of keloid scars. Additionally, symptoms of pain and burning are commonly associated with these scars. In such cases, best practice guidelines currently emphasize the importance of multimodal therapy. Even so, appropriate goals must be set and the patient must be made aware that lesions can redevelop or even worsen on recurrence. Currently the only two viable treatment options for mature keloids are to either (a) monitor the scars routinely, or (b) to excise them and administer adjuvant therapy. Excision and primary closure alone invariably results in recurrence.

Adjuvant therapies for keloids include steroid injection, radiation, cryotherapy, laser, and antitumor or immunosuppressive agents. In general, the first line adjuvant is intralesional corticosteroid injections. Steroids have also demonstrated synergistic benefits when utilized with other modalities such as laser, radiotherapy, and cryotherapy. Triamcinolone acetonide at 10 mg/mL is generally tried initially, and if no response occurs, a 40 mg/mL concentration is attempted. Injection into the dense scar is often painful and associated with risk of infiltration into the surrounding normal tissue. Early, rapidly proliferating lesions respond best to steroid injections whereas slowly growing, mature keloids

respond poorly. Intraoperative and postoperative intralesional steroid therapy following excision has been shown to reduce recurrence rates to below 50%.^{64,72}

A short course of low-dose (20 Gy) radiotherapy to the keloid excision wound immediately after excision has been shown in numerous retrospective studies to reduce the rate of recurrence.^{73–75} A more recent prospective study, however, found recurrence rates of 72% at 1 year following excision and radiotherapy.⁷⁶ The immediate and long-term risks of radiation therapy, including the potential for malignant transformation, demand further study. Nonetheless, radiation therapy may reasonably be considered in adults with lesions refractory to other modalities.

Cryotherapy is a low-cost and effective method of treating select keloid scars. In multiple retrospective series, complete flattening or greater than 80% volume reduction occurred in 73–85% of lesions treated with liquid nitrogen.^{77–79} Early lesions of less than 1–2 years' duration appeared to have more favorable results. A subsequent prospective study examining cryotherapy of both hypertrophic and keloid scars found an even greater response with hypertrophic scars.⁸⁰ In this study, a good to excellent response was found in 78.9% of hypertrophic scars versus only 50.9% of keloids. Interpretation, however, is limited by vague evaluative criteria. Though the mechanism is unknown, the effects of cryotherapy appear to be synergistic with steroid injection.^{81,82} Yet despite its potential efficacy, cryotherapy has been limited to treatment of small lesions due to adverse side effects such as pain, blistering, lengthy wound healing, skin atrophy, and near-universal dyspigmentation.

As with other modalities in scar treatment, critical evaluation of lasers in keloid treatment has been complicated by small studies with vague diagnostic criteria, inconsistent evaluation and lack of long-term follow-up. Additionally, the multitude of laser types and treatment algorithms complicates direct comparative study. A 1995 study in *The Lancet*, for instance, found decreased pruritus and scar height with pulsed-dye laser treatment but did not distinguish keloid from hypertrophic scar and had follow-up limited to 6 months.⁸³ Though lasers have been utilized clinically for scar treatment for nearly 20 years, prudent use is best advised pending further study. Our experience has been favorable when combining pulsed-dye laser with intralesional steroid injection for keloids.

In summary, while there is yet no single modality completely effective in keloid management, multimodality approaches offer some promise. Current treatment algorithms promote the use of corticosteroids, silicone sheeting, and compression garments as first-line therapy, especially in small, early keloids.³⁸ Large, recalcitrant keloids can carry significant morbidity and are very challenging to treat. Optimal management may include surgery, steroids, radiation, or other modalities and are best performed by a surgeon or center with a focus on keloid treatment.

Emerging treatments

A promising new therapeutic modality is the local delivery of antitumor and immunomodulatory drugs for the treatment of keloid and hypertrophic scars. The use of immunomodulatory agents such as TGF- β modulators, interferons (IFNs),

5-fluorouracil (5-FU), and bleomycin allow us to exploit our growing understanding of scar biology to offer new solutions to age-old problems. While the body of data is still small, early evidence suggests that these drugs have potential for the safe and effective treatment of excessive scarring.

TGF- β s are profibrotic growth factors that attract and stimulate fibroblasts to increase collagen synthesis and decrease ECM breakdown. Changes in TGF- β activity have been linked to fibrotic diseases of the kidney, lung, and heart. A robust body of literature implicates the TGF- β family as a major determinant of scar morphology.^{84,85} This increased knowledge of signaling pathways and TGF- β isomers has been translated into new therapeutic avenues for exploration. For instance, initial phase I/II trials of prophylactically injected recombinant TGF- β 3 have demonstrated an improvement in the appearance of scars.⁸⁶

IFNs are anti-fibrotic cytokines that suppress the formation of collagen.⁸⁷ Trials of intralesional injections of IFN- α 2b and later IFN- γ as both monotherapy and postsurgical adjuvant therapy have yielded positive results. An early study found reduced keloid recurrence rates of 18.7% with adjuvant IFN- α 2b injection versus 51.2% with surgery alone at a 7 month follow-up.⁸⁸ Subsequent studies, however, have been mixed. Some trials have shown early recurrence when interferons are used as monotherapy while others indicate benefits with combined therapy.^{89,90} Nevertheless, targeted therapy with IFN continues to be alluring from a biochemical standpoint, and deserves further investigation.

Antineoplastic agents 5-FU and bleomycin are additional promising pharmacologic candidates for treatment of pathologic scarring. Small RCTs have built upon the experience of large clinical series to provide preliminary evidence for the efficacy of 5-FU in keloid treatment.^{91–93} In one study, side-by-side application of 5-FU and steroid injections on median sternotomy keloids suggested equal efficacy for 5-FU without the side effects of skin atrophy, hypopigmentation, or telangiectasia seen with steroid treatment.⁹⁴ Though not yet fully understood, the effects of 5-FU may be mediated in part through interference with the TGF- β signaling pathway.⁹⁵ Bleomycin, on the other hand, is thought to act by binding DNA and preventing mitosis.⁹⁶ Initial clinical studies from Europe suggest efficacy without systemic toxicity.^{97,98} While results have thus far been favorable for both these agents, larger-scale studies are needed to validate the findings of early small studies.

Scar revision

Introduction

Plastic surgery education and techniques enable practitioners to offer surgical, nonsurgical, and combined treatment modalities to patients with scars. Treatment is therefore based on understanding of underlying pathology rather than limited to a certain tool or device. For the most disfiguring and debilitating scars, surgery is often a necessary component of therapy, if not the only effective therapy. After careful analysis of a scar's characteristics (morphology, maturity, distortion of tissues) and appropriate application of noninvasive measures,

the plastic surgeon can then turn to an array of surgical tools to treat a difficult scar.

Indications

Patients seek scar revision for a multitude of reasons. As discussed earlier, scars carry both physical and psychologic implications. Understanding what role these factors play in a patient's desire for treatment is important in setting and reaching patient expectations.

Scars eliciting physical symptoms should be examined carefully. Patients will often report discomfort and tightness as a result of scar contraction. An exquisitely painful scar should be examined for Tinel's sign, which may suggest entrapment of a cutaneous nerve. Excision or repair of a neuroma is often an important part of scar revision. Scar contractures across joints, frequently seen in burn patients, can result in limited functionality and reduced range of motion. In such cases, treatment should be directed at restoration of function and be carried out in conjunction with aggressive physical therapy to prevent recurrence.

Disfiguring scars can cause significant personal and social burdens. The surgeon should be sympathetic and nonjudgmental as these scars may be reminders of past trauma and current hardship. Administering care alongside a mental health professional can help distinguish and address complicating psychological issues. For the surgeon, extra care must be taken in these circumstances to confirm realistic expectations and reinforce the goals of care.

Timing

Timing of scar revision should reflect an assessment of scar maturity and an understanding of the underlying biology. A soft supple mature scar is the ideal starting point from which to consider revision. Immature scars contain the fragile blood vessels of neovascularization, which may bleed excessively during surgery. In addition, the tissue in and around immature scars is more edematous and less mobile, complicating local tissue rearrangement. Tissue primed for scar revision should be maximally mobile and soft.

Surgical timing should therefore be based on clinical exam, though some suggest delay for at least 18 months. Interval exams should be used to monitor a scar until one can be certain of maturity. Any uncertainty in scar maturity should prompt the physician to wait longer. This can often be difficult in patients who are eager for a solution. Nonoperative management such as massage and silicone sheeting should be offered to the patient during this period as it can help maximize outcome. A patient's compliance with nonoperative measures can also help serve as a measure of his or her motivations and expectations. This can also be a time to build a relationship of trust between the patient and physician. Those eager to proceed may not have realistic expectations and should be counseled accordingly. Patients should be advised that early revision will increase the risk of complications and will reset the clock on wound healing and scar maturity.

Hypertrophic scarring can be thought of as a chronic inflammatory condition. Early surgery is all the more plagued by immobility and bleeding. Unless planning to excise the

entire scar, surgery should be deferred until scar maturity is achieved. This can often take longer than with normotrophic scars and should again be dictated by clinical exam. Dr. Mil-lard's principle "When in doubt, don't!" bears stressing.¹

Planning

In addition to timing, several other factors are important to consider when planning for surgical scar revision. For complex reconstructions involving multiple areas, management is best directed at larger areas initially. For instance, burn scars involving the head and neck should start with resurfacing of the cervicofacial region before addressing the ectropion.

Surgeons must also determine if each scar is best treated by single or multistaged revision. Single-staged operations include both simple direct excisions and more complex soft-tissue rearrangements. Unless an initial wound was widened due to infection and dehiscence, direct excision alone is rarely effective. When applicable, however, preoperative suturing and on-table tissue expansion can be used to decrease tension on a wound after direct excision. Undermining and advancement of skin edges similarly allow for reapproximation without tension. This can be performed asymmetrically to change the degree of tension and deformity in neighboring tissue. Subsequent use of a tension off-loading dressing can further minimize scarring.³⁷

Serial excision and tissue expansion are staged strategies for scar revision. While seemingly simplistic, staged serial excisions of scars may provide the best results (Fig. 14.8). Two or three serial excisions of a large scar may accomplish what is hazardous or even impossible in a single stage operation. Serial excision is accomplished by circumferentially excising the margin of a scar, then undermining and advancing bordering normal tissue. The pliability of the normal tissue should be assessed before making the incision. This will dictate how much scar is safe to excise and timing of subsequent stages.

Tissue expansion is an alternative method for staged scar revision. This procedure enables the body to grow extra skin for use in reconstruction through the placement of expanders under the skin. Tissue expansion has been especially valuable in scalp reconstruction of patients with burn alopecia, though it does carry the additional risk of infection associated with implant placement and requires two procedures for insertion and subsequent removal.

Scar release

Scarring is a three-dimensional process that often extends from superficial to deep tissue. Scar contracture in deep layers can result in puckering and tethering of the overlying tissue. This can occur even in the absence of superficial injury. Fat necrosis following blunt tissue trauma, for instance, can result in a concave skin defect without laceration. Treatment of tethered scar requires release from the underlying tissue and sometimes interposition of muscle or fascia. Soft-tissue fillers, fat autograft, and acellular dermis have all been used successfully to fill depressed scars, although long-term data are lacking.^{99–101}

Acne scarring requires special consideration as the multiple pitted scars of "ice-pick" acne can be disfiguring and result in

Fig. 14.8 (A–C) Serial excision.

considerable psychological stress for the patient. Mild to moderate acne scars may benefit from resurfacing procedures such as those using CO₂ laser or chemical peels to even out contour deformities.¹⁰² More serious acne scars, however, require formal excision to achieve adequate depth. Focal excision with release of tethered tissue can be extremely effective but should first be applied to one or two test lesions to assess patient-specific results.

Principles of tissue rearrangement

The surgical approach to scar revision should be guided by the same principles outlined for scar prevention. These include atraumatic technique, tensionless closure, and proper skin eversion. Scar revision that involves tissue rearrangement, discussed further below, also requires consideration of anatomic landmarks and lines of tension. Restoration of anatomic landmarks such as the vermillion border, eyelid position, or alar base should take priority over minimizing scar characteristics.¹ The use of local flaps in the face to prevent distortion of anatomic landmarks is an example of this principle. In this instance, the larger scar of a flap is preferred when local tissue recruitment would result in deformity of facial landmarks. Scar revision should similarly focus on restoring anatomic structures to their correct location.

Scars should be hidden in the resting lines of skin tension. Presented originally in 1861, Karl Langer's eponymous "lines" resulted from examination of vertical wounds left by circular stab marks into a cadaver.¹⁰³ Reorientation of a scar to these lines allows for the least tension across a wound.¹⁰⁴ This is achieved in scar revision surgery via tissue rearrangement techniques such as Z-plasty. The lines of resting tension form the basis for the aesthetic units and subunits that dictate facial surgery.^{104,105} The face, however, is dynamic and patients should be cautioned that scars may become more apparent with changes in expression.

Scar elongation and irregularization are other principles that reflect consideration of tension lines caused by the scars

themselves. Myofibroblasts in a mature scar can cause scar contracture within the axis of the scar. A long, straight scar will result in uniform contracture in one axis, causing greater deformity in the surrounding tissue and greater depression of the scar. This tight scar can lead to limitations in movement. Furthermore, the change in contour may be aesthetically displeasing. Thus, in addition to reorienting the scar, local tissue rearrangement techniques break up the length of the original scar by incorporating neighboring tissue. A longer scar relaxes the pull on each end of the scar towards the center of the scar. Contractile forces are displaced into the axis perpendicular to the length of the scar. Multiple applications of this technique result in an irregular scar, wherein contractile forces are dispersed into multiple axes. This, in turn, results in less tissue deformation and a more easily camouflaged scar.

Scar revision techniques

Local tissue rearrangement requires an understanding of tissue properties, careful planning, and meticulous technique. When applied successfully, these simple but fundamental principles embody the art of plastic surgery and enable the surgeon to attain goals of scar reorientation, elongation, and irregularization necessary for effectively addressing difficult scars.

Though some argument exists, the Z-plasty technique can be traced back at least as far as Horner in 1837 and Denonvilliers in 1854.¹⁰⁶ Their procedure for transposing triangular flaps to relieve cicatricial ectropion has evolved over time into the modern Z-plasty. In current nomenclature, Z-plasty refers to transposition of two triangular flaps, usually of equal size and equal angle, into each other's defect.

Planning and performing Z-plasty requires an understanding of geometric principles. The first published mathematical analysis came from Limberg in 1929.¹⁰⁷ Through the Pythagorean theorem he revealed the theoretical gains in length achievable with changes in the angle of the lateral limbs

Table 14.4 Z-plasty gains in length

Angle of lateral limb of Z-plasty	Theoretical gain in length of central limb (%)
30	25
45	50
60	75
75	100
90	120

(Table 14.4).¹⁰⁸ In practical application, however, the elasticity of skin and rigidity of scar create unequal deformation of the central and lateral limbs.¹⁰⁹ This deformation results in lower gains in length *in vivo* than would be expected in theory. Deformational forces are magnified with smaller flaps and with serial Z-plasties. Nevertheless, proper execution of a Z-plasty is essential to accomplishing four fundamental functions: lengthening a scar, breaking up a line, moving tissue, and obliterating or creating a web or cleft (Box 14.3).¹¹⁰

Z-plasties have been further divided into simple, planimetric, skew, and multiple. The simple or stereometric Z-plasty has two flaps of equal angle and length (Fig. 14.9). Traditionally, these flaps are raised at 60° as this angle offers the best balance between elongation in the axis of the scar and the creation of tension forces pulling perpendicular to the scar. Last-minute flap revisions can be avoided by incising and transposing one flap to determine excursion accurately *in vivo* before cutting the second flap.

The planimetric Z-plasty is a variation of the classic Z-plasty that maintains the flaps in the same plane (Fig. 14.10).¹¹¹ By minimizing the amount of rotation and excising redundant tissue, this flap design avoids the contours and depressions created by simple Z-plasty. Flaps may theoretically be designed with lateral limb angles ranging from 60° to 90°, though most often they are planned at 75° angles. The planimetric Z-plasty is ideal for scar releases on flat surfaces where lengthening is the primary objective and contour deformities would be suboptimal.

Skew Z-plasties have lateral limbs departing at different angles from one another (Fig. 14.11). This flap has been suggested when anatomic landmarks mandate asymmetric movement of one flap. Furnas and Fischer's topographic study in dogs revealed that the narrow flap transposed easily but was likely to form a "dog ear", while the wider flap was difficult to transpose and caused more stretch at its base.¹⁰⁹ This is counterintuitive to some degree as the narrow flap has to travel through a larger arc of rotation to traverse the wide flap. For this reason, deformational forces created by skew Z-plasty flaps can be difficult to predict and its use should be avoided.

BOX 14.3 The four fundamental functions of Z-plasty

1. To lengthen a scar
2. To break up a straight line
3. To move tissues from one area to another
4. To obliterate or create a web or cleft

Fig. 14.9 (A–C) Simple Z-plasty.

Fig. 14.10 Planimetric Z-plasty.

Multiple-flap Z-plasty refers to multiple Z-plasties along a scar length as well as Z-plasties designed with more than two flaps (Fig. 14.12). When performing multiple Z-plasties in series, the previous Z-plasty exerts deformational forces on the tissue of the next Z-plasty, further limiting the actual gain in length. A single large Z-plasty at a specific angle will therefore create more length than multiple small Z-plasties at that same angle. A large Z-plasty, however, is not always in keeping with the aesthetic and functional goals of a scar revision. Numerous Z-plasties utilizing multiple flaps have been devised. Among them, the Limberg's four-flap and Mustarde's "jumping man" five-flap Z-plasties are frequently used for release of first-web-space contractures (Fig. 14.13).^{107,112}

Regardless of design, care must be taken to widen the tip of flaps to avoid tip necrosis.¹¹³ The thickness of flaps is

dictated by the quality and location of the tissue. Scars often have distorted and unreliable blood supply, therefore thicker flaps are necessary. In unscarred tissue, care must be taken to elevate the subdermal vascular plexus to include the cutaneous microvasculature in the flap.

Other scar revision techniques include V-Y and Y-V advancement flaps, W-plasty and geometric broken line. V-Y and Y-V advancement flaps allow for the incorporation of adjacent tissue without the threat to vasculature necessary for Z-plasty (Fig. 14.14). These flaps are not transposed and therefore do not require undermining. Like Z-plasties, these flaps can be carried out in tandem through careful flap design.

W-plasty and geometric broken line are techniques for scar irregularization (Figs. 14.15, 14.16).¹¹⁴ W-plasty uses a zigzag pattern excision of the scar followed by reapproximation of

Fig. 14.11 Skew Z-plasty. (Reproduced from Furnas DW. Transposition of the screw z-plasty. *Br J Plast Surg.* 1966;19:88–89.)

Fig. 14.13 Four-flap Z-plasty.

Fig. 14.14 V-Y and Y-V advancement flaps.

Fig. 14.15 W-plasty. RSTL, relaxed skin tension lines.

small interdigitated limbs. There is no elongation of the scar and tissue is removed, therefore a net increase in tension is produced in the axis perpendicular to the scar. In contrast, Z-plasty trades relaxation in the axis of scar for tension perpendicular to the scar, resulting in no change in overall tension. Albert F. Borges has suggested W-plasty as a good revision technique in facial scars that are not in the resting lines of skin tension and do not have excessive tension across them.¹¹⁴

Lastly, geometric broken line is a refined technique wherein 5–6 mm randomly distributed triangles, squares, trapezoids, and semicircles are incised at the wound edge with reciprocating shapes planned opposite them. However, this technique is challenging and labor-intensive, though it may have some utility in further camouflaging facial scars that cross aesthetic subunits.

Postoperative care and follow-up

Initial postoperative care should be directed towards optimal wound healing, including adequate nutrition, blood sugar control, smoking cessation, and activity precautions. Long-term scar reduction techniques are aimed at prevention and treatment. Following a revision, scar reduction can be achieved through use of a tension off-loading device. Aggressive use of taping, silicone sheeting, compression, and scar massage may also provide modest improvement. More detailed follow-up care should be dictated by patient-specific factors. Regardless of complexity, however, both the patient and physician benefit from long-term follow-up as this provides an opportunity to evaluate the efficacy of any treatment strategies.

Skin graft

Saja S. Scherer-Pietramaggiore, Giorgio Pietramaggiore, and Dennis P. Orgill

▶ Access video and video lecture content for this chapter online at expertconsult.com

SYNOPSIS

- History of skin grafting mirrors many of the important advances of plastic surgery.
- There are complex biologic mechanisms that allow skin grafts to take.
- There are a variety of types of skin grafts that can be selected based on clinical application.
- Technique should be adjusted to avoid most complications.
- There are exciting areas of research that will help minimize donor site size and improve function and appearance of skin grafts.

Skin grafting is a technique for the transfer of cutaneous tissue from one site of the body to another, often to cover large defects. Depending on the thickness of the dermis of graft that is harvested, skin grafts are defined as full-thickness or split-thickness. See [Fig. 15.1](#), [Box 15.1](#) and [Video 15.1](#) ▶ for a step-by-step guide on how to prepare a skin graft.

Anatomy and physiology

The skin represents approximately 8% of our total body weight, with a surface area of 1.2–2.2 m². The skin is 0.5–4.0 mm thick and covers the entire external surface of the body, including the walls of the external acoustic meatus and the lateral tympanic membrane. The main function of skin is to protect body contents from the environment, including pathogens, temperature, and excessive water loss. Insulation, temperature regulation, sensation, immune function, and the synthesis of vitamin D are all critical functions of the skin. Skin loses regenerative capacity when lesioned down to the lower dermis and results in scar tissue when injured.

Epidermis

Skin has a complex three-dimensional structure characterized by two overlapping layers, the epidermis and the dermis. The epidermis, as the nervous system, derives after gastrulation from the neuroectoderm. Epidermis is the outer or upper layer of skin, which is a thin, semitransparent, water-impermeable tissue, consisting primarily of keratinocytes. These cells form a multilayered keratinized epithelium, similar to a wall of bricks. The basement membrane separates the epidermis from the dermal tissue and consists of a protein structure produced by basal keratinocytes. Basal keratinocytes are partially differentiated stem cells of the epidermis that provide the proliferative and regenerative capacity of the skin epithelium. The epithelium is metabolically active and continuously self-renews to maintain an efficient barrier function. Cellular homeostatic regulation is, as a consequence, very important: too little proliferation would bring a loss of barrier and excessive activity to hyperproliferative disorders, such as psoriasis. Homeostasis is granted by the basal epidermal cells, which periodically cycle, executing their program of terminal differentiation, a process that takes approximately 28 days. The differentiation of the keratinocytes is characterized by the progressive production of alpha-keratin, with migration towards the surface until the cells lose their intercellular connections (desmosomes), die, and become corneal lamina.

During this process, called cornification, basal keratinocytes produce tonofilaments (precursor of keratin) and then transform into the stratum spinosum as the desmosomes stretch the cells into spikes visible with a microscope. In the plasmalemma, the tonofilaments are connected to the desmosomes. Cells next start to produce keratohyalin, which aggregates in dense and basophilic granules, giving the name to the stratum granulosum. In these granules a histidine-rich protein, profilaggrin, becomes progressively filaggrin, which ultimately acts as a glue to keep keratin filaments together once the cells die and the cell membrane degrades.

As the cells divide and move up through the epidermis they eventually transform into the stratum corneum, a layer

Historical perspective

Skin is the largest human organ, covering 1.7 m² in the average adult. It serves as an essential barrier with mechanical, immunological, and aesthetic functions. Skin transplantation has long fascinated humans and there is evidence that skin grafts were performed in India as early as 1500 BC for traumatic nasal amputation. Modern science has taught us much about the anatomy and physiology of skin.

Gaspare Tagliacozzi, one of the first reconstructive surgeons (1545–1599),¹ described pedicled skin flaps from the arm for nasal reconstruction in patients. Two centuries later research was conducted by Giuseppe Baronio (1750–1811), who performed and published for the first time skin grafts in a lamb (*Degli innesti animali*, 1804).² Jonathan Warren in Boston and Joseph Pancoast in Philadelphia were among the first to perform and describe autologous full-thickness skin grafting in humans using the arm as a donor site. Paul Bert, a French politician, showed in his thesis that skin graft survival is only possible if blood vessels of the recipient site are able to revascularize the graft. His work popularized this technique.³ For the techniques, Reverdin, a French student, described harvesting skin islands with the scalpel tip with transfer to a first web space wound.⁴ He discovered that these skin islands not only temporarily covered, but also actively stimulated, wound healing. Reverdin's work was rapidly accepted and performed by multiple surgeons in the US. The term "dermoepidermoid"

graft was introduced by Leopold Ollier (1830–1900), who also first used the split-thickness skin graft (STSG) to close entire wounds.⁵ He noticed that healing was achieved faster and wound contraction was minimized. The German surgeon Carl Thiersch (1822–1895) further developed the technique of skin grafting and introduced the concept of wound bed preparation by removing granulation tissue to achieve a clean wound bed to facilitate graft revascularization. The English ophthalmologist, John Reissberg Wolfe (1824–1904), from Glasgow, published the use of a full-thickness skin graft for ectropium correction.

With the development of skin harvest techniques the number of publications reporting clinical results of skin grafts increased exponentially. Later, James Carlton Tanner (1921–1996) revolutionized burn surgery by the introduction of meshing to expand skin grafts in order to cover larger wounds with minimal donor site morbidity.⁶

Reverdin's technique was modified by John S Davis (1872–1946), who elevated the skin with a needle in 1914 to facilitate harvesting, a technique that he called "pinch graft".⁴ In 1920 Ricardo Finochietto (1888–1962) developed a knife to elevate larger skin areas manually by controlling the thickness of the skin graft. Ten years later, the invention of the shave blade by Humby further facilitated skin harvest.

The introduction of the mechanical dermatome of Padgett-Hood and Reese in 1940 and 8 years later the development of the electric dermatome by Harry Brown significantly facilitated skin harvest of large surfaces in a controlled manner.

Fig. 15.1 Excision and grafting. A combination of excision and grafting is the preferred approach for the treatment of deep dermal burns. The burn is excised (**A**) until a viable wound bed is reached, as evidenced by capillary bleeding. The graft (**B**) is a thin layer of skin, consisting of epidermis and partial-thickness dermis, which is harvested from a nonaffected area, often the anterior thigh or abdomen. The skin graft is placed over the excised area (**C**) and attached with sutures or staples. Reduction of the size of skin-graft donor sites can be accomplished by making the split-thickness skin graft into a “mesh graft” by placing multiple small slits in the graft, allowing it to expand by up to six times the original area. (Adapted from Orgill DP. Excision and skin grafting of thermal burns. *N Engl J Med.* 2009;360:893–901.)

of dead cells, which ultimately is highly mechanically and chemically resistant due to chemical bonds between lipids and proteins. It is thought that cells die as the increasing proteins in their cytoplasm start to activate lysosomes. The stratum corneum provides an extremely effective barrier layer to keep water in and microorganisms out.

Also contained within the epidermis are melanocytes, Langerhans cells, Merkel cells, and sensitive nerves. Around

10% of the epidermal cells are represented by melanocytes, which derive from the neural crest. These complex dendritic cells produce melanin granules (contained in the melanosomes) that are then transported through dendrites into keratinocytes, providing color to the skin and protecting basal epithelial nuclei from ultraviolet damage. Melanocytes are anchored to the basal lamina by hemidesmosomes, but do not have desmosomic connections with other cells.

BOX 15.1 How to perform a skin graft

- Prepare the wound bed for grafting (debridement and hemostasis)
- Estimate the needed skin graft size
- Clean the donor site from any residual disinfection (i.e. Betadine)
- Apply paraffin on the donor site
- Set the dermatome at 0.2 mm thickness
- Stretch the donor site skin
- Apply the dermatome at a 45° angle and apply light pressure
- Slide the dermatome along the skin while an assistant is lifting the skin graft with two forceps
- Lift the dermatome upwards when the desired size of graft is obtained
- Dress the donor site with Vaseline gauze, dry gauze and bandages
- Fix the bandage generously to the skin (e.g. thigh) to avoid sliding down of the dressing
- Spread evenly the graft (dermal site of the graft upwards) on a dermal carrier (rough surface of the carrier upwards) of the desired size (1 : 1.5, 1 : 3, etc).
- Pass the graft through the graft mesher paying attention that it does not detach from the dermal carrier
- Apply the graft on the recipient site by sutures, surgical staples or fibrin glue
- When indicated apply a bolster dressing by placing Vaseline gauze on the skin graft, followed by a cotton sponge impregnated with Betadine or saline solution and tight sutures (4/0 nylon or polypropylene) from the opposite wound margins together at the center of the defect
- First dressing change should be around 5–7 days post-op

Langerhans cells are the immune cells of the epidermis and are important in generating a response to foreign agents, playing an important role in allograft rejection and contact dermatitis. These cells are situated in the stratum spinosum and, with long dendrites, slide between epithelial cells, without desmosomic connections to them. Langerhans cells share several features with macrophages of connective tissues.

Merkel cells are commonly found in the epidermis of palms, soles, nail beds, oral and genital areas. Merkel cells act as mechanoreceptors and thus are responsible for neurosensory transmission. These cells reside in the basal layer of the epidermis, often protruding into the dermal layer like nails. Merkel cells are connected by desmosomes to the neighboring cells.

Skin adnexal structures are epidermal derivatives that invaginate into the dermis with a lining of epithelial cells. They include hair follicles, sweat and sebaceous glands. These structures provide the basis for re-epithelialization following the harvest of a split-thickness skin graft (STSG).

Sensitive nerve supply to the skin is rich and extends through the basement membrane into the epidermis. Nerve fibers also go to skin adnexal organs that allow hair to become erect and sweat glands to secrete.

Dermis

The dermis is a tough fibrous layer that provides the mechanical features of the skin. It is composed primarily of collagens, glycosaminoglycans, and elastins. Skin grafts without the dermis result in a closed but often unstable skin. Grafting a part of the dermis is therefore very important to consider in terms of functionality of the future skin.

The upper part of the dermis has a particular architectural organization that is called papillar and contains blood vessels and nerve fibers. The papillar layer of dermis consists of fine collagenous fibers that form an undulating interface with the overlying basement membrane and epidermis. This structure increases the contact area between dermis and epidermis, allowing for maximal mechanical stability of the two layers and an exchange surface for diffusion. Deeper, we find the reticular dermis, with increasingly thicker collagenous fibers (mainly of type I) as we move toward the subcutaneous tissue. The reticular dermis has larger collagenous fibers with substantial strength. The mechanical properties of the dermis are critical to allow movement while providing stability and protection from mechanical trauma. The dermis is remarkably self-healing, mainly due to the presence and activation of myofibroblasts following injury.

Blood vessel supply of the skin

Dermal vascularization is particularly important, as blood vessels are not directly present in the relatively more metabolically active epidermal layer, glands, and hair follicles. Blood vessels set up a rich superficial plexus just underneath the basement membrane in the papillary dermis, facilitating nutrient transport to the epidermis. The blood vessels in the papillary dermis are arranged in the papillary plexus, with a rich network of capillaries in the papillae, which come in close contact with the epidermis. Deeper in the dermis is the reticular plexus from which small vessels distribute to the subcutaneous and deep dermal tissues to vascularize adnexal organs,

including the hair follicle bulb. Arterial capillaries generate venous plexi, which have the same distribution of arterial vasculature. In the deep layers of dermis it is possible to find several arteriovenous anastomoses, particularly at the extremities (hands, feet, ears), where they exhibit strong muscular sphincters. The function of these structures is mainly under the control of the visceral nervous system, with the main function of thermoregulation and intravascular volume redistribution.

Blind-ended lymphatic structures are present in the dermis from where they connect to the reticular plexus and to larger vessels in the subcutaneous tissue. In this region, lymphatic vessels are larger, with valves, and drain into deeper lymphatic vessels called regional collectors. In the skin the lymphatic drainage is very active with multiple interconnections enabling lymphatic exchange. Circumferential skin and subcutaneous damage can therefore lead to problematic lymphatic stasis in extremities or in the genital area.

Stem cells and regeneration of skin

Basal epithelial keratinocytes are the committed stem cells of the epidermis. Constant self-renewal provides a new protective layer at the skin surface.⁷⁻¹² Hair follicles contain multipotent stem cells that are activated upon the start of a new hair cycle and upon wounding to provide cells for hair follicle and epidermal regeneration. In the hair follicle, stem cells reside in the bulge area. Bulge cells are relatively quiescent compared with other cells within the follicle.^{9,10} However, during the hair cycle, bulge cells are stimulated to exit the stem cell niche, proliferate,¹³ and differentiate to form the various cell types of the hair follicle.¹⁴ In addition, bulge cells can be recruited during wound healing to support re-epithelialization.^{15,16}

The relative importance and exact contribution of bulge cells to wound healing are currently unknown as areas of the body such as the palms and soles that lack hair follicles still exhibit normal healing.

Hair follicles

Hair differentiates in a craniocaudal direction, 9 weeks after gestation, as mesenchymal cells populate the skin to form the dermis. Specialized cells in the dermal layer stimulate epithelial cells to proliferate and migrate downward into the epidermis, forming hair canals. The complete developed hair follicle contains an ectoderm-derived matrix and an underlying mesoderm-derived follicular papilla. There are three bulges that attach to the hair bulb. At the base the erector muscle develops, the middle part gives rise to the sebaceous gland, and the superficial bulge develops into an apocrine unit (Fig. 15.2).

Histological structures of the hair follicle can be divided as follows. The part that reaches from the entrance of the hair follicle into the skin to the apocrine gland is the infundibulum. The zone between the apocrine gland and the sebaceous gland is referred to as the isthmus. The stem of the hair follicle is located between the sebaceous gland and the base of the erector muscle. The bulb is the deepest part of the hair follicle and contains the follicular matrix and papilla. This part is growing and regenerates the hair after injury. If the bulb is lesioned the hair will not recover from injury.

Fig. 15.2 Skin grafts. **(A)** Split-thickness skin grafts (STSGs) are the preferred approach for the treatment of large superficial skin defects such as dermal burns. STSGs consist of the partial-thickness dermis and the epidermis. Depending on the thickness, STSGs are referred to as thin or thick STSGs. In thick STSGs superficial hair follicles can be included into the graft and restore hair growth and functional sweat glands in the future skin. **(B)** Full-thickness skin grafts are limited in availability and are used in the reconstruction of aesthetic (face) or functional (hand) body areas. The graft is usually taken from behind the ear, or the inguinal or elbow fold. The graft consists of the complete dermal and epidermal layer, including hair follicles and glandular structures. **(C)** Hair follicle: histological structures of the hair follicle. The presence of epidermal cells as far as the bulb explains the fast re-epithelialization after STSG harvest at the donor site. The infundibulum reaches from the entrance of the hair follicle into the skin to the apocrine gland. The zone between the apocrine gland and the sebaceous gland is referred to as the isthmus. The stem of the hair follicle is located between the sebaceous gland and the base of the erector muscle. The bulb is the deepest part of the hair follicle and contains the follicular matrix and papilla. This part grows and regenerates the hair after injury. If the bulb is lesioned the hair will not recover from injury. (Adapted from Orgill DP. Excision and skin grafting of thermal burns. *N Engl J Med.* 2009;360:893–901.⁶¹)

Follicles can be found in different phases: anagen (proliferating phase), catagen (regression phase), and telogen (resting phase).

Although no new hair follicles are made postnatally, the lower portion of the hair follicle regenerates in order to produce new hair. Some of this capacity has been linked to the presence of multipotent epithelial stem cells. These cells can be found in the lowest permanent portion of the hair follicle – the bulge.¹³ Bulge stem cells are activated during the transition from telogen to anagen, to restart hair growth.

Glandular structures

Sebaceous glands are small saccular structures residing throughout the dermis, but are more common in thicker areas. These glands produce lipid-rich sebum on the surface of the skin and around the hair shaft. The function of sebum is still partially unknown but probably is linked to protection of the hair and contributes to the impermeabilization of the skin, giving protection from stings and parasites. Sebaceous glands are particularly large on the face, trunk, shoulders, and genital and perianal regions. When excessive quantities of sebum are produced – such as during puberty – the duct can be obstructed and ultimately may become infected or form cysts.

Sweat glands are divided into eccrine and apocrine glands. There are numerous eccrine glands in every region of the body except the tympanic membranes, lips, nail bed, nipples and clitoris. Their body has a glomerular structure and they excrete a clear odorless, hypotonic liquid. The secretion is stimulated mainly by an increase in body temperature, with the exception of some regions, such as palms, face, and axilla, where the main stimulus is emotional.

Apocrine glands are found exclusively in the axillar, perianal, periumbilical, areolar, preputial, scrotal, pubic and vulvar areas. While their structure is similar to that of the eccrine glands, these glands differ as regards the quality of their excretions, which are characterized by a thick milky, protein-rich fluid, which has a striking odor after bacterial colonization.

Science

Mechanisms of skin graft take

Skin grafting is the transfer of autologous skin cells left in anatomic order but without an intact blood supply. Therefore time and the recipient surrounding conditions limit the vitality. The operative procedure allows for nearly immediate

Fig. 15.3 The concept of revascularization of the graft. Skin graft take is characterized by three main phases: (1) Plasma imbibition: the graft is initially nourished by the plasma circulation from the wound side. (2) Blood vessel connection: three different theories of how the skin graft revascularizes on the wound bed are described: (a) graft vessels regress and leave a basal lamina infrastructure followed by ingrowth of host epithelial cell ingrowth; (b) the reconnection of graft and host open ends; and (c) the ingrowth of endothelial cells from the host into the graft. (3) Revascularization of the skin graft. (Adapted from Capla JM, Ceradini DJ, Tepper OM, et al. Skin graft vascularization involves precisely regulated regression and replacement of endothelial cells through both angiogenesis and vasculogenesis. *Plast Reconstr Surg.* 2006;117: 836–844.)

coverage of large wound areas. Meshed grafts allow further expansion of skin but leave multiple small wounds that are re-epithelialized, mainly from the mesh within a few days. Skin can also be expanded through multiple small skin island grafts (as in Reverdin's technique) that stimulate granulation tissue, probably by excreting growth factors. In STSGs, keratinocytes on the basal layer show high proliferation rates, which may ultimately stimulate growth factor excretion.¹⁷

Three phases of skin graft take are commonly described: (1) serum imbibition; (2) revascularization; and (3) maturation (Fig. 15.3).

Serum imbibition

In the first days, before the graft revascularizes, oxygen and nutrients diffusing through the plasma between the graft and the wound bed will nourish the skin graft. Huebscher in 1888¹⁸ and Goldmann in 1894¹⁹ theorized that skin grafts might be nourished by host fluid before vascularization of the graft occurs. They referred to this as "plasmatic circulation."^{18,19} Later, Converse *et al.*²⁰ altered the term to "serum imbibition", as fibrinogen changes into fibrin that fixes the skin graft on to the wound bed in the absence of real plasmatic flow. Converse's studies show that skin grafts gain up to 40% of their initial weight within the first 24 hours after grafting and then this gain is reduced to 5% at 1 week postgrafting.²⁰ In the first hours, passive absorption of serum from the wound bed causes edema, which resolves when the revascularization is functional (see Fig. 15.3).

Revascularization

Revascularization is critical for long-term skin graft survival. Early studies in the 19th century^{21–24} suggested a connection between the wound bed and graft vessels, referred to as

inosculation,^{3,18,19,25} but the mechanism of revascularization remained unclear for many years.

Three hypotheses of revascularization are supported by the literature, each of them probably contributing to the process: anastomosis, neovascularization, and endothelial cell ingrowth. Anastomosis is the process of reconnection between the blood vessels in the recipient site wound bed and the graft.^{21,23,24,26–28} Neovascularization is characterized by new vessel ingrowth from the recipient site into the skin graft. The last mechanism describes endothelial cell proliferation and sliding from the recipient site, utilizing pre-existing vascular basal lamina as a structure, while in the graft endothelial cells gradually degenerate.^{22,24,29–31}

The process of revascularization begins as early as 24–48 hours after grafting.^{32,33} Many authors describe vessel ingrowth mainly from the wound bed and less so from the wound margins, since no significant increase in blood vessels was seen in graft margins after skin grafting.^{21,24,32–35} Studies supporting vessel ingrowth from the host as the main mechanism of skin graft revascularization have been controversial with respect to time course and the mechanism of host-graft vessel interactions.^{23,36} Some early studies demonstrated by intravenous injection with radioisotopes that blood flow in the graft was established 4 days after grafting.³⁷ Similarly, studies using India ink showed graft vessel stain as early as 2 days post-grafting.²³ More recently, it was demonstrated, using a transgenic tie2/pacZ mouse model, that vessel ingrowth appears in the periphery of the graft (following blood vessel regression in the graft) from day 3 until day 21.³⁸ Zarem *et al.*²² suggested that the process of vascularization of full-thickness skin grafts in the mouse is dominated by vascular ingrowth from the recipient using a modified transparent skin chamber. Henry and Friedman³⁶ proposed the theory that endothelial cells of superficial graft vessels degenerate and that host vessels profit from the basement membrane-covered infrastructure for new vessel ingrowth. In 1967, other investigators confirmed this theory using the graft hamster cheek pouch and showed a similar vessel pattern before and after grafting.³⁹ Converse and Ballantyne further investigated endothelial cell ingrowth into the graft using diaphorase, a marker of viable vascular endothelium. They found increased diaphorase levels in the graft bed 4 days after grafting, supporting the theory of vascular ingrowth from the host. As very few functional anastomoses were present, the authors concluded that both mechanisms, inosculation and vascular ingrowth, were important in the process of revascularization.³¹ Vessel regression was also supported by NADH diaphorase activity loss during the first 4 days after grafting that was probably taken up by new vessel ingrowth.^{29,38,39} The conclusion that endothelial cells utilize preformed tunnels of basal lamina was triggered by the observation that initially empty graft vessels subsequently became infiltrated with leukocytes and that ingrowing vessels used the white blood cell-filled channel as a conduit.²² Later studies showed a central refilling of the graft vasculature as early as 48 hours, leading to the conclusion that early anastomosis between host and graft vessels may play a major role in graft revascularization, as vessel growth occurs at about 5 $\mu\text{m}/\text{hour}$ and angiogenesis would take at least 5 days to reach the 600- μm -thick murine dermis.^{22,40} In 1987 Demarchez *et al.*⁴¹ supported this hypothesis by grafting athymic mice with human STSGs. Double labeling of cross-reacting antifactor VIII and a human-specific

antitype IV collagen antibody showed initial anastomosis between graft and host vessels. Murine host cells gradually replaced vascular structure and the extracellular matrix of the skin graft. Later studies confirmed this hypothesis by observing a similar blood vessel network of the skin graft at the donor site and after revascularization of the graft between 96 and 120 hours after grafting.³²

Capla *et al.* further showed that about 20% of blood vessels supporting the microcirculation on day 7 after grafting occurred by bone marrow-derived endothelial progenitor cell-derived vasculogenesis.³⁸ Recent studies measured increased levels of growth factors related to hypoxia-induced angiogenesis (hypoxia-inducible factor-1 and vascular endothelial growth factor) 24–240 hours after grafting, a process that may also contribute to host vessel ingrowth (see Fig. 15.3).³²

Maturation

Once the skin graft is completely integrated, the same graft and surrounding tissues remodel and contract, similar to the last phase of wound healing after re-epithelialization is complete. Skin grafts take at least 1 year to complete maturation, with the extension of this process continuing for several years in burn victims and children. Scars from skin grafts can continue to improve for a number of years, often making prolonged conservative therapy worth considering.

Skin graft vascularization contributes to prevent underlying tissue contraction. Fibroblasts from surrounding tissues and from blood circulation become activated and repopulate the wound at the interface between the graft and the recipient site. As collagen is deposited, cross-linking allows the extracellular matrix to resist mechanical insults. Fibroblasts develop fibers called alpha-smooth-muscle actin (alpha-SMA) that exert contractile forces on the extracellular matrix. The development of alpha-SMA coincides with the differentiation of fibroblasts into myofibroblasts and wound contraction. During wound maturation, the epithelium from the edges of the wound produces a basal lamina on the open surface while sliding across and progressively covering the immature granulation tissue.

During the remodeling phase, all immature blood vessels necessary to support the initial phases regress and eventually disappear. The remodeling phase of wound healing is the longest, lasting from several months up to years.

Skin appendages and functional structures

Hair follicles, sweat glands, and dermal nerves can often be transferred within thick STSGs and full-thickness skin grafts (see Fig. 15.2). Thin STSGs will not allow the transfer of hair or other adnexal glands, as the regenerating bulb is not harvested. Hair regrowth can occur in STSGs but, due to the shallow depth of harvest, is rather unlikely. Full-thickness and composite grafts will show hair regrowth 2–3 months after grafting.

It is still unclear how nerves regrow into the skin graft. Studies demonstrated that recipient nerves use the basal lamina infrastructure of degenerated blood vessels and Schwann cells of donor nerves to grow. Although histological images reveal similar neural structures between healthy skin and integrated skin grafts, patients report abnormal sensation, including hypersensitivity and pain, up to 1 year after grafting. Usually patients regain sensitivity of the grafted area after 1 year, but the result is not completely normal.

Neural reconnection to sweat glands will reactivate their function up to 3 months after grafting. For this reason, moisturizing of the skin graft is advised for at least 3 months to avoid dryness.

Full-thickness skin grafts include skin appendages that can survive and be functional at the recipient side, while STSGs do not contain the deep structure skin appendages and remain without glandular function or hair growth.

Clinical application

Skin wounds that extend into the deep dermis heal through the mechanisms of scarring and wound contraction. For large

Fig. 15.4 Split-thickness donor sites. Split-thickness donor sites are commonly chosen from the anterior thigh or abdomen. Color-matched and aesthetically less evident areas can only be chosen if healthy skin is available. In burn patients with only limited availability of nonaffected skin, skin will be taken from any part of the body. Face and hands are preferentially spared from skin harvest. (Adapted from Knipper P. *Mission: plastic surgery under challenging conditions*. Maitrice Orthopédique. 2002:118 and 2003:112.)

Table 15.1 Definition of origin of the skin graft

Graft type	Graft origin: donor and recipient
Autograft	Same subject
Homograft	Same species
Isograft	Different subject Same genetic background
Allograft	Different subjects Same species
Hetero- or xenograft	Different subjects Different species

(Adapted from Andreassi A, Bilenchi B, Biagioli M, et al. Classification and pathophysiology of skin grafts. *Clin Dermatol*. 2005;23.)

Table 15.2 Indications, advantages, and disadvantages of thin split-thickness skin graft (STSG), thick STSG, and full-thickness skin graft (FTSG)

	Indications	Advantages	Disadvantages
Thin STSG	Debrided burn wounds Chronic wounds with less vascularized wound beds Exposed flap areas Acute well-vascularized wounds	Fast donor site re-epithelialization Multiple possibilities to reharvest the same area Good graft take	Contraction of the skin graft Graft quality limited because of minimal dermal thickness
Thick STSG	Same indications as thin STSG	Less secondary graft contraction compared to thin STSG Graft more stable because of thicker dermal layer Good graft take	Slower donor site re-epithelialization
FTSG	Reconstruction of functional areas such as in the face or hand Noninfected, well-vascularized wound beds	Minimal to no secondary graft contraction Excellent skin quality, stability Hair regrowth and skin appendage function	Limited availability Nontake risk is higher in a less vascularized wound bed

wounds this process leaves the body at risk of infection and when it occurs around joints, this can lead to significant scar contractures that affect functionality. For example, in anterior neck wounds, the contractile processes can be so strong that, over time, the chin can be fixed to the chest, often with a thick scar. Also, wounds that are left open for months to years can degenerate into skin cancer (Marjolin's ulcer). For these reasons, methods that rapidly facilitate wound coverage or resurfacing are desired.

Skin grafting is still the gold standard to cover large areas of skin loss. The concept is to take skin from an area where

the donor site will heal with minimal scarring and transplant it to an area of need. As skin grafting always leaves some sort of scar, donor site considerations are important when balancing the needs of the recipient site for a given skin graft.

Skin grafts can be of different origin (Table 15.1), from different anatomical sites (Fig. 15.4), and can be harvested in different thicknesses (Table 15.2). Depending on the histological level of the graft the skin graft type is classified by thin and thick STSGs, full-thickness skin grafts, and composite grafts (see Fig. 15.2). Skin grafts are further classified according to their thickness into thin (0.15–0.3 mm, Thiersch–Ollier), intermediate (0.3–0.45 mm, Blair–Brown), and thick (0.45–0.6 mm, Padgett). Skin grafts thicker than 0.6 mm usually correspond to full-thickness skin grafts and are called Wolfe–Krause grafts.^{42–44}

Split-thickness skin graft

The thickness of the dermal layer classifies the STSG as either thin or thick. An STSG consists of epidermis and a variable amount of superficial to profound (papillary) dermis. As the dermis is responsible for the viscoelastic property of the skin, it is crucial for stability of the future skin. The amount of dermis grafted is key to the outcome: body areas with high mechanical friction are ideally grafted with thicker dermal layers. If donor sites do not allow this, skin quality can be improved with a combination of skin and dermal substitute grafts.

Thin STSGs include the epidermis and a thin layer of the dermis (see Fig. 15.2). STSGs are commonly taken from the lateral thighs and trunk (see Fig. 15.4). They do not include the full length of appendages and are therefore unlikely to grow hair or to develop full sweat gland function. The main advantage of thin STSGs is the reduced morbidity of the donor site and the possibility of performing multiple harvests from the same donor area about 2 weeks after the previous harvest. Although thinner grafts allow for more frequent reharvest, they result in additional wound contraction. The clinician must weigh the advantages and disadvantages of these conflicting goals when deciding the thickness of the graft.

Fig. 15.5 Donor site preparation. Bleeding is one of the most important complications of excision and grafting. To reduce the severity of bleeding during excision, the fatty tissue under the graft can be infiltrated with a solution of epinephrine diluted in saline ("tumescent technique"). (Modified from King M, Bewes P. *Skin grafts and flaps: the general method for split skin grafting*. In: *Primary Surgery*, Vol. 2. Trauma. Oxford: Oxford University Press; 2009. By permission of Oxford University Press Inc.)

Fig. 15.6 Split-thickness harvest with a manual knife. Alternatively, if no electrically driven dermatome is available, skin grafts can be carefully harvested with a manual knife. This procedure requires experience and harvest of even thickness is difficult. (Adapted from Knipper P. *Mission: plastic surgery under challenging conditions*. Maitrise Orthopédique. 2002:118 and 2003:112.)

Thick STSGs include more dermis with a greater number of full hair follicles and glandular structures (see Fig. 15.2). These grafts will likely develop some hair growth and sweat gland function about 2–3 months after grafting. Thick STSGs are commonly selected to cover areas of high mechanical friction, such as joints, plantar soles, and the palm. Since hair regrowth is common in thick STSGs, the donor site should be carefully chosen to avoid unpleasant hair growth. The sensitivity and function of sweat glands are often better in thick than in thin STSGs. Because of decreased nutrient diffusion, thick grafts require a better recipient wound than thin grafts during the revascularization process. Therefore, thick grafts should be avoided in unhealthy wound beds such as in chronic ulcers. The donor site usually heals with more obvious scarring and discoloration but less graft contraction.

Technique

To reduce bleeding during skin harvest some surgeons prefer to infiltrate the donor site area primarily with epinephrine diluted in saline subcutaneously (tumescent technique: Fig. 15.5). If small to medium-sized areas of skin are needed and a dermatome is not available, surgeons can skillfully take skin grafts with a surgical knife or with the oscillating Goulian knife (Fig. 15.6). The disadvantage of skin grafts taken manually is the difficulty of achieving uniform depth that can result in aesthetically unpleasant donor and recipient site skin pattern. To increase the uniformity and expedite the harvest of skin grafts, a number of electrical or air-powered dermatomes have been designed to take uniform small to large skin grafts. Powered dermatomes have adjustable guards to set the graft thickness. There is a fair amount of variability in thickness depending on how hard the operator pushes on the dermatome. Drum dermatomes are precision instruments that can take large graft areas reliably (Fig. 15.7). They require

Fig. 15.7 Split-thickness harvest and grafting. (A) Split-thickness skin graft (STSG) harvest with an electrically driven dermatome at the anterior thigh. (B) The skin graft should be positioned flat on the mesh template: this can be performed by multiple slits to (C) expand the graft up to six times its original size. (D) Meshed STSGs are ideal to cover large and uneven wounds. Stapler fixation is a time-saving method to fix large grafts. (Adapted from Orgill DP. *Excision and skin grafting of thermal burns*. N Engl J Med. 2009;360:893–901.)

placement of adhesive on the skin and an oscillatory movement by the operator.

When possible, harvesting the skin graft first and covering the donor site will avoid contamination from the wound. When the excisional preparation of the recipient site needs to be performed first, a separate instrument set-up for the donor site can be considered. The size of the graft needed should be accurately measured prior to harvest. The graft thickness can be adjusted by a lever near the end of the dermatome between 0.1 and 1.0 mm. The surgeon presses the dermatome at 45° to the skin surface on to the tissue and moves the device from distal to proximal with uniform pressure and speed (see Fig. 15.7). A second assistant can pick up the skin graft with two anatomical forceps during the harvest process to avoid damage of the graft. If the desired length is taken, the dermatome will cut the edge when elevating it while running the motor. Keeping the graft moist with saline-impregnated gauze is of vital importance if not immediately grafted.

Larger skin grafts should be incised with an 11 knife multiple times to allow wound fluid drainage and prevent collections between the skin graft and the wound bed.

Fig. 15.8 Non-meshed split-thickness skin graft coverage 18 months after debridement of 2nd deep burn injury of the hands. Note excellent aesthetic and functional results.

Meshed skin graft

STSGs can be enlarged up to six times their original size. Enlargement of the graft can vary from just a few manually applied perforations with an 11 blade to a systematic enlargement with a hand-powered meshing device (mesher) that applies multiple slits at regular intervals (see Fig. 15.7). Meshed grafts are often used following large burns when the wound area exceeds available healthy donor sites. Meshed skin grafts are also very helpful to cover irregular geometric surfaces, such as around joints, as they minimize folds in the graft. Development of contractures should be taken into consideration in functional areas. If meshing is not necessary or should be avoided in important aesthetic or functional areas, such as face, neck and hands, the graft should be perforated multiple times to allow fluid removal under the graft (pie-crusting) that can minimize the risk of hematoma, seroma, or infection under the graft. Unmeshed STSG can achieve excellent aesthetic and functional results (Fig. 15.8). Using different mesh templates, from 1:1 to 1:9, can regulate the extent of the enlargement of meshed grafts. The most commonly used mesh ratio is 1:1.5 in smaller wounds, while a mesh ratio of 1:3 and 1:6 is often needed to cover large burns.

Meshing devices are manual and come with different plastic templates where the skin graft is placed on upside down. The graft should be taken with anatomical forceps to avoid mechanical damage. The mesh gaps will be subsequently filled by keratinocytes from the skin stripes

(Fig. 15.9). This process takes longer with higher mesh expansion ratios. Since grafted cells excrete growth factors, underlying granulation tissue will be stimulated until full re-epithelialization occurs. Aesthetically unpleasant hypergranulation in the open areas of the mesh are therefore more often seen in large mesh ratios often leading to an uneven cobblestone-like skin relief (Fig. 15.10). Meshed skin grafts leave unsightly long-term results that need to be considered when selecting this technique. Very thin meshed skin grafts used in combination with dermal substitutes or keratinocyte cultures are other strategies to mitigate the result (see Fig. 15.8).

Full-thickness skin graft

Full-thickness skin and composite grafts are limited in availability but show excellent function and sensitivity after engraftment. Full-thickness grafts should be considered in the

Fig. 15.9 Meshed split-thickness skin graft (STSG) and re-epithelialization. The pattern of the meshed STSG is evident even after completely healed skin and is more evident with the enlargement ratio used. Therefore, surgeons possibly prefer to expand with 1:1.5–1:2 ratios as maximum. (A) The meshed skin graft can be fixed with staples or sutures. (B) Open surfaces will be gradually re-epithelialized from the skin stripes. In largely expanded grafts the stimulation of the wound bed from the engrafting cells leads to hypergranulation, resulting in an unpleasant aesthetic pattern. (Adapted from Orgill DP. *Excision and skin grafting of thermal burns*. N Engl J Med. 2009;360:893–901.)

Fig. 15.10 Uneven skin relief, “cobblestone” pattern in a left forearm 3 years after deep burn injury, debridement and coverage by a 1:3 ratio meshed split-thickness skin graft.

reconstruction of aesthetically dominant (face) or functionally important (hand) areas. Full-thickness grafts from the retroauricular region and above the eyebrows are an excellent choice to maintain tissue quality and color of the surrounding skin in the face (Fig. 15.11). If needed, foreskin can also be used and in adults retroauricular skin is helpful in face reconstruction. Also, excess skin from the upper eyelid and submental area can be taken into consideration for full-thickness

Fig. 15.11 Full-thickness donor sites. Full-thickness skin graft (FTSG) donor sites are limited and require primary wound closure or split-thickness skin grafting after harvest. FTSG are indicated in the reconstruction of smaller lesions in aesthetic (face) or functional areas (hand). Larger FTSG can be taken from the buttock fold and the infra-abdominal fold. Ideal for reconstruction of the hand is the hypothenar area and the anterior wrist fold. The main axis of the elliptically shaped hypothenar graft should be positioned slightly dorsal to the glabrous–skin border to avoid a hypersensitive scar. For face reconstruction, FTSGs are taken from the retroauricular or, often used in children, the superior eyebrow regions for optimal color match. The inguinal fold is frequently used because of good aesthetic outcome at the donor site. Other areas are the subclavicular, the infra-abdominal, and the elbow fold as well as the inner upper arm. (Adapted from Knipper P. *Mission: plastic surgery under challenging conditions*. Maîtrise Orthopédique. 2002:118 and 2003:112.)

reconstruction if the patient is comfortable with an aesthetic-like intervention.

In hand reconstruction, elbow crease and wrist fold grafts have been described but should be avoided in cultures where these donor site scars may result in stigmatization of the patient as they can be associated with suicide. Hypothenar skin is useful for glabrous reconstruction but can leave a painful scar that can cause an unpleasant sensation if the hand is positioned on a table in a relaxed position. Therefore, full-thickness skin graft from the hypothenar area should be harvested elliptical with the main axis and slightly more dorsal in relation to the glabrous–skin border (see Fig. 15.11).

Full-thickness skin grafts are taken in an area where loose surrounding skin is available to achieve primary closure. Skin grafts can be designed elliptical and excised with a knife. Harvesting should be carried out trying not to elevate the underlying tissue. Most of the full-thickness grafts need defatting and this can be easily performed by spreading the graft over the index finger and trimming the fat tissue tangentially to the skin. Defatting of the graft will encourage graft take (Fig. 15.12).

Composite graft

Composite grafts include a layer of subcutaneous fat tissue under the dermal and epidermal layer. The donor sites are principally the same as the full-thickness donor sites. Since fat tissue is less vascularized and more vulnerable to ischemia, optimal revascularization is needed in order to achieve graft survival. Composite grafts can be used in children as they show a remarkable capacity to revascularize thicker grafts. Some surgeons use composite grafts to reconstruct the nasal tip, the alar, and the columella in cleft lip patients.⁴⁵

Over time, the appearance of skin grafts tends to improve in both color and texture. Nevertheless, skin grafts rarely have the aesthetic appearance of normal skin and patients should be advised about the likely final appearance of the graft.

Skin fixation and dressing

Once the autologous skin is grafted on to the wound site the revascularization depends on multiple factors. One of the most important factors to achieve stable taking is the immobility of the graft during the revascularization process. An open technique requires labor-intensive monitoring on the graft and any fluid that is formed beneath the graft is rolled out with a cotton-tipped applicator. More often, skin grafts are fixed through a series of sutures and overlying compressive dressing materials (bolster: Fig. 15.13). Scattered sutures through the graft on to the wound bed can additionally immobilize larger skin grafts. If large and multiple skin grafts are placed, as frequently needed in burn victims, fixation can be performed with staplers to shorten operation time. Staples are painful when removed and may be overgrown by skin, especially in large skin grafts. Vacuum-assisted pressure devices can be used with a protective interface of petroleum gauze or a silicone sheet to permit continuous compression on to the graft and fluid removal. The suction dressing is especially useful if fast mobilization is desired in patients with wounds in joint regions or the lower extremities (see Fig. 15.13). Compression to stabilize the graft on to the wound bed should be performed until 5–10 days after grafting, when the graft is usually stable and wound areas are completely closed.

Fig. 15.12 Full-thickness skin graft (FTSG) harvest and preparation. FTSGs should be designed elliptically to achieve primary wound closure without deforming surrounding tissues. This fact is usually given if a length:width ratio of 1:3 is followed. **(A)** After sharp excision of the graft the surgeon should elevate the graft if possible without fat tissue and protect the graft by handling it with a skin hook or anatomical forceps. **(B)** Defatting is an important process to avoid fat necrosis after grafting and to facilitate direct revascularization of the wound bed. The graft can be easily defatted with scissors by stretching the graft upside down over the index finger. **(C)** To allow fluid exit from the wound bed, FTSG should be incised with a sharp knife in multiple sites. (Adapted from Knipper P. *Mission: plastic surgery under challenging conditions*. Maîtrise Orthopédique. 2002:118 and 2003:112.)

Fig. 15.13 Fixation of a skin graft. Skin grafts require precise contact with the wound surface, and fluid collections and micromovements are to be avoided. A bolster dressing is an excellent method to press and stabilize smaller skin grafts on to the wound, particularly in the face or hand areas. **(A)** The graft is placed and sutured on to the wound and sutures are left intentionally long. **(B)** A first layer of nonadhesive fat dressing is placed on the graft and covered with a bolster of cotton or gauze that is sutured face to face over the second layer. **(C)** The second layer will exert mild pressure on to the graft that stabilizes the graft and allows fluid exit into the bolster dressing. **(D)** The bolster dressing will precisely adapt the skin graft on to the wound bed to optimize the conditions for the revascularization process. **(E)** Vacuum-assisted closure dressing to fix skin grafts: the fixation of the skin graft is an elegant method, especially if larger and uneven areas that cover joints are grafted. Continuous suction and compression on to the wound bed ensure fluid removal and stabilization of the graft. The skin graft will be fixated as usual and the first dressing should be either a nonadhesive perforated silicone dressing or a petroleum gauze to avoid maceration of the graft by the open polyurethane foam. Some surgeons use the moist white foam without interface to fix the graft. (A, C Adapted from Knipper P. *Mission: plastic surgery under challenging conditions*. Maîtrise Orthopédique. 2002:118 and 2003:112. B, Adapted from Chase RA. *Atlas of Hand Surgery*. Philadelphia: WB Saunders; 1974.)

Splints can be used as adjuncts if the risk of wound contraction is high, such as in chin scar release or in joint and web space release of the hand. These splints or casts should be worn up to several months after grafting, in the beginning 24 hours per day, later during the night, to avoid the loss of mobility. Physiotherapy and scar massage are also important elements for obtaining better results with skin grafts.

Negative-pressure wound-healing devices also make very effective bolsters, especially on large grafted surfaces and chronic ulcers.^{46–48}

Sealants

Fibrin glue can also be helpful to assist skin graft fixation. In this case, some surgeons spray fibrin glue on to the skin graft dermis just before placing it on to the wound site. The fibrin network may even act as a provisory extracellular matrix under the graft.⁴⁹

First dressing change

The first dressing change should occur once the skin graft is revascularized and has a stable physical connection to the wound bed. Early dressing change around the third day after grafting may allow for predicting the “take rate” of the graft but risks secondary graft loss through shear forces that disturb nascent vessel connections. More commonly the dressings are taken off for the first time 5–10 days after grafting.

Recipient site considerations

Before planning a skin graft, several factors have to be taken into consideration to achieve optimal tissue cover at the wound site. The wound bed quality has to be optimized for a successful “take” of the graft and the skin color, thickness, and mechanical resistance of the donor site area should ideally match the recipient site skin quality. Wound conditions often found in chronic or insufficiently debrided burn wounds and characterized by low wound bed vascularization or high bacterial loads will not allow skin grafts to be taken.

Wound bed preparation

The successful engraftment of skin grafts highly depends on the quality of the wound bed. Revascularization particularly depends on a vital recipient wound bed. A good quantity of blood vessels near the surface is critical in order to support graft viability. Irradiated, ischemic and scar tissue, bone, and tendon do not ordinarily have sufficient blood supply to allow the skin graft to take. If highly vascularized peritendon and periosteum are still intact, skin grafts can be performed. In chronic wounds re-epithelialization occurs at the wound margins that can grow into the tissue and may inhibit the lateral reconnections of the graft. Therefore, wound margins should be sharply excised with a blade before grafting.

Experimental data suggest that the bacterial level must be brought down below the critical level of 10^5 bacteria per gram of tissue to allow a skin graft to take. The practical problem with quantitative bacterial cultures is that it takes about 48 hours to obtain the result, long after the decision to graft is typically made. As a result, this methodology seems most commonly applied to research studies. Surgeons often take a fairly aggressive approach to making sure all necrotic tissue

has been debrided and that the wound is clinically “clean” prior to grafting.

Wound debris or necrotic tissue physically inhibits and chemically slows ingrowth of blood vessels into the skin graft. Wounds that were left open for several days contain high bacterial loads and therefore need to be extensively debrided before skin grafting. Preparation of the recipient site commonly occurs by sharp excision, but can also be performed using a variety of other debridement techniques, including laser, water jet, and ultrasound as well as standard dressing changes. Surgeons have learned over time that a “granulating” wound has a high likelihood of taking a skin graft. Active bleeding of the wound bed will likely lead to blood collection between the graft and the wound bed, inhibiting graft take. Accurate hemostasis can be performed with bipolar cautery and larger blood vessels can be ligated with fine resorbable sutures.

If tendons or bones are exposed without peritendon or periosteum, the surrounding soft tissue can often be adapted to cover critical structures before skin grafting. Small areas of tendons and bones can either be prepared by vacuum-assisted closure therapy to grow granulation tissue from the sides or dermal substitutes can be used to cover functional structures.

Functional consideration

Skin grafts can often provide functional and aesthetic skin reconstruction. Consideration needs to be given to the size of graft needed, the degree of wound contraction expected, the color and texture of the skin required, and the need for adnexal glands. The amount of wound contraction expected is inversely related to the amount of dermis in the skin graft.

Full-thickness grafts, those that take the entire epidermis and dermis, maximally restrain contractile forces and give excellent cosmetic results. Full-thickness skin grafts are frequently used for nipple-areola reconstruction, syndactyly release, or ectropion release. Full-thickness grafts are in short supply and can be augmented by tissue expansion prior to harvesting full-thickness skin grafts.

Very thin grafts such as epidermal grafts result in a donor site that heals quickly with minimal contraction but provide little constraint to wound contraction. The surgeon can use this as an advantage if wound contraction is desired. For example, on large scalp wounds or abdominal wounds, wound contraction may be desired to keep the skin graft as small as possible while pulling the wound edges together over time. Secondary excision of the contracted skin graft and primary wound closure can be performed in a second stage to achieve best functional and aesthetic results.

As the skin thickness varies throughout the body, a variety of skin thicknesses are available for use. For example, full-thickness upper eyelid skin is very thin but provides good resistance to wound contraction. Thicker skin is available in the trunk and leg region, where thick STSGs can be taken, leaving enough adnexal structures and dermal thickness to minimize donor site scarring.

Aesthetic considerations

Skin color is determined by a complicated integration of skin texture, melanin pigmentation, and blood flow. In general,

replacement of tissue from a similar or adjacent site will give the best color match. In the face, this is often the most critical aesthetic area and choosing donor sites such as supraclavicular, posterior auricular, upper eyelid or scalp skin grafts can often lead to an excellent color match. For darker areas of the skin, such as the nipple–areola complex, grafts from the contralateral areola or genitalia have been used. More commonly today, skin grafts in this area can be tattooed with vegetable dyes to give an excellent color match.

Skin texture is most commonly an issue when dealing with glabrous skin (palms and soles of feet). In this case, placing a nonglabrous skin graft to cover these areas can result in a very unnatural look, often with significant color match differences. Glabrous skin grafts are obviously in short supply but can be harvested from the hypothenar eminence. Skin adnexal glands are difficult to replace but can sometimes be successfully transferred with full-thickness grafts.

Donor site considerations

The obligatory scarring or discoloration associated with donor sites must be considered when taking a skin graft (Fig. 15.14). For large surface area burns, the surgeon must use whatever donor site is available to close the wound; in contrast, for smaller grafts, a thorough discussion of the donor site possibilities with the potential risks and benefits allows for the best skin match with the least iatrogenic damages.

Common donor sites include the thigh, trunk, and buttocks, regions frequently covered by clothing (see Fig. 15.4).

When defects of the face need to be covered, full-thickness skin grafts are often preferred. The donor area for a graft on the face should be preferably chosen from among the scalp, neck, and supraclavicular area to obtain the best color match. Important aspects are the thickness, color, and texture of the graft, which should closely match those of the recipient site.

Eyelid skin, which is thin with a few glandular structures, is generally best replaced by eyelid skin. Thick, highly glandular nasal skin can be replaced by skin from the nasolabial folds, supraclavicular area, or anterior auricular area.

In trauma, avulsed (degloved) skin can often be prepared by extensive defatting and regrafted primarily⁵⁰ or stored and used later.

Fig. 15.14 Donor site three years after split-thickness skin graft taken with a dermatome at the forearm. Note slight hypopigmentation.

Full-thickness donor sites in the head and neck are pre- and postauricular regions (the first is generally thicker), nasolabial crease, supraclavicular region, eyelids, and neck.

Other common regions include the inguinal crease, which is often used to cover large defects. In this case it is important to harvest laterally and away from potentially hair-bearing regions of the pubis. This area generally heals well and is hidden (see Fig. 15.11).

In nipple–areola reconstruction after mastectomy, a full-thickness graft from the contralateral region is often taken in combination with a full-thickness graft from the groin.

Donor sites from full-thickness skin grafts are generally closed primarily. Particular attention should be taken when supraclavicular donor sites are used, as this region is prone to develop hypertrophic scars. Sometimes large donor sites that cannot heal primarily are used for covering extensive defects, for example, in the face or joints. In this case, an STSG can be used to cover the donor site.

Donor site dressing

Topical gauze soaked with diluted epinephrine solution is useful to stop bleeding at the donor site and can be left until the operation is ended, adding an analgesic effect. The donor site of an STSG generally heals (re-epithelializes) in 7–21 days depending on the size and depth of the graft taken and the age of the patient. A myriad of donor site dressings are available with multiple studies on a variety of products. Traditionally, fine-meshed gauze, often impregnated with a petroleum-based product, is placed over the wound and fixed in place. Cotton gauze is placed over this and removed a day or two after the operation. The wound heals under this dressing and the dressing spontaneously comes off when healed. The advantages of this type of dressing system are its simplicity, low cost, and minimal wound care requirement. The work of Winter in the early 1960s⁵¹ showed that a moist wound heals faster. As a consequence many have advocated a simple semioclusive, adhesive, semipermeable polyurethane dressing, although it promotes serum accumulation between the wound and the dressing that should be evacuated by a drain or a syringe. This process can be labor-intensive for a busy inpatient service or difficult to manage on an outpatient basis. In addition, when an infection develops, it can rapidly spread to the entire donor site area with this dressing.

A large number of other dressings, including silver-based, absorptive, and biological, have been studied. In most of the cases the donor site heals spontaneously, thus simple impregnated gauze is still the gold standard. When some complications occur, the harvest site can deepen and become a full-thickness defect, mainly due to infections in the elderly, infants, or critically ill patients. As a consequence, excision and grafting of the donor site may be required.

Skin graft storage

Skin grafts can be stored on a moist gauze at 4°C for up to 2 weeks, although the viability decreases over time. Experimentally, storage can be extended using cell culture media. For degloving injuries, the skin can be defatted acutely and reapplied as a full-thickness graft.

Complications

Hematoma

Any liquid between the wound and skin graft can impair skin graft take. Bleeding represents one of the most important complications after excision and grafting, with up to 100–200 mL of blood for every 1% of body surface area that is excised, particularly from the scalp.⁵² The surgeon must be certain that bleeding has stopped prior to dressing the wound. Suture ligation or cautery can be used to control larger bleeding vessels; oozing can be controlled with pressure and/or pharmacological methods such as topical thrombin, epinephrine, or fibrin glue. To reduce bleeding during excision the area can be primarily injected with epinephrine diluted in saline (tumescent technique: see Fig. 15.5).⁵³ As discussed above, incisions of the graft should be done to allow fluid evacuation through a compressive or suction dressing.

Seroma

Serum imbibition is essential for early skin graft survival. Excessive serum, such as a seroma, will prevent or delay skin graft take. Seromas are better tolerated than hematomas, and adequate fenestrations (pie crusting) can prevent this problem.

Infection

When skin graft infections occur, pus often accumulates beneath the skin graft and can rapidly spread. If an infection is found early, prompt incision and drainage of the fluid beneath the graft can often salvage some or all of the skin graft. A large number of dressings have been developed that carry a variety of topical antimicrobial agents. Silver nitrate, mafenide acetate, and silver ion dressings are commonly used. Bacteria seem not to develop resistance easily to silver products, making these products desirable.

A contaminated wound will not heal and will reject a graft. Some microorganisms, such as *Pseudomonas* spp., can contaminate the wound and cause nonpurulent infections. Even systemic or nonskin-localized infections have been proven to delay or prevent skin graft taking.

Nontake

Unfavorable conditions such as malnutrition, vasculitis, malignant diseases, steroids, and chemotherapeutic medications have all been shown to cause or accelerate nontake of the graft.

Wound contraction

Wounds covered with skin grafts can still undergo wound contraction leading to a scar contracture. After the acute inflammation phase the contraction starts. Fibroblasts from surrounding tissues and from blood circulation start to be activated and repopulate the wound between the graft and the wound bed. Cells at the interface need to build new collagen-rich tissue to replace fibrin and anchor the graft to the wound bed. While fibrin is crucial for early cell migration in the wound bed, collagen deposition allows wound maturation. As collagen is deposited, cross-linking occurs so that the

extracellular matrix becomes mechanically resistant. This increase in mechanical resistance allows mechanical interaction with fibroblasts that develop fibers called alpha-SMA. The development of alpha-SMA coincides with the differentiation of fibroblasts into myofibroblasts that induce wound contraction.

Instability

Shear forces are a major cause of skin graft failure that can disrupt the nascent fragile blood vessel connections. Later, thin skin grafts have less collagen content and are prone to delamination due to shear forces.

Cosmetic issues

Unpleasant cobblestone-like patterns of meshed STSGs are much more prominent than nonmeshed or full-thickness grafts. Color differences are a common problem if donor sites could not be optimally chosen. If excess skin surrounds the grafted area, the skin graft can be excised in multiple steps until primary closure can be reached.

Donor site

Infection at donor sites can occur from bacterial contamination during the operation or in the postoperative period. These infections are treated with topical antimicrobial agents, including silver dressings. The delay in healing of donor sites due to infection can lead to hypertrophic scar formation. Hypertrophic scar or keloid formation can also result from deep donor sites or in patients with a propensity for scarring. Itching is a common reaction to donor sites as well as hypersensitivity to changes in temperature.

Future

Dermal substitutes

Burke *et al.* first described a collagen–glycosaminoglycan scaffold to treat dermal defects in the early 1980s.⁵⁴ Dermal substitutes (Table 15.3) are widely used in large burn injuries, when skin lesions are so extensive and unaffected donor skin areas are often limited. Cadaver skin (allograft) or dermal substitutes can be used initially to cover large defects. Dermal substitutes can also be used to improve functional and aesthetic outcome. Dermal regeneration is very limited in human skin and full-thickness skin defects heal by secondary intention with scar tissue formation. The difference between scar tissue and healthy skin besides the aesthetic appearance is the viscoelasticity and therefore stability. Scar tissue shows histological parallel-oriented collagen fibers, while healthy dermis consists of randomly oriented collagen fibers. In some patients and for restricted donor sites, keratinocyte cultures or very thin STSGs can be attempted to close full-thickness defects. The resulting skin is usually fragile and dry, leading to reopening and ulcers through normal mechanical friction. This poses a particular problem if functional structures underlie the new thin skin. The introduction of the first commercially available skin substitute, Integra®, is a bovine-derived collagen type I cross-linked matrix with glycosaminoglycans that is similar to the dermal structure and covered by a silicone

Table 15.3 Permanent and temporary dermal and epidermal skin substitutes

Product	Tissue – cells	Manufacturing availability	Origin
Epicel® (Genzyme, MA)	Epidermis – cultured epidermal autograft (CEA) sheets	Tissue cultures expanded in the laboratory over several weeks	Autologous and xenogeneic (residual amounts of murine cells)
ReCell® (Avita Medical, UK)	Epidermis – autologous epidermal cells Dermis – fibroblasts; cell suspension, delivered with a spray	Bedside approach (about 30 minutes required)	Autologous
Cellutome™ Epidermal Harvesting System (KCI, TX)	Epidermis – autologous epidermal islands delivered on a dressing	Bedside approach (about 60 minutes required)	Autologous
Integra® (Integra Lifesciences, NJ)	Dermis – bovine tendon type I collagen and glycosaminoglycans on a silicone sheet	On the shelf	Xenogeneic
MatriDerm® (MedSkin Solutions Dr. Suwelack, Germany)	Dermis – bovine acellular non-crosslinked, coated with elastin	On the shelf	Xenogeneic
Alloderm® (LifeCell Corporation, NJ)	Dermis – human acellular lyophilized cadaver dermis	On the shelf	Allogeneic
Dermagraft® (Organogenesis, MA)	Dermis – human fibroblasts on polyglycolic–polylactic acid mesh	On the shelf	Allogeneic
EZ Derm (Mölnlycke Health Care, Sweden)	Dermis – porcine aldehyde cross-linked dermal collagen	On the shelf	Xenogeneic
Oasis® Matrix (Smith and Nephew, TN)	Dermis – porcine acellular small intestine submucosa	On the shelf	Xenogeneic
Allograft	Composite – cryopreserved cadaveric skin	On the shelf	Allogeneic
Apligraf® (Organogenesis, MA)	Composite – neonatal human fibroblasts in bovine type I collagen Neonatal human keratinocytes	On the shelf	Allogeneic/xenogeneic

sheet to recreate temporarily the function of the epidermis. Integra® can be applied to a vascularized wound bed followed by blood vessels and cell growth into the collagen matrix to create a vascularized neodermis after 2–3 weeks. During the avascular period, the dermal graft is very sensitive to infection, one of the main disadvantages of the two-step strategy.

Once revascularization is accomplished, the silicone layer can be removed and the epidermal replacement can be granted by either keratinocyte cultures or a thin STSG (Fig. 15.15). To improve dermal graft integration, surgeons have successfully seeded dermal substitutes with keratinocytes.²³ Newer clinical studies show that small areas of exposed tendon or bone without remaining peritendineum or periosteum can be successfully grafted with Integra®.

After the invention of Integra®, a number of other human- and animal-derived dermal substitutes are now commercially available. Another synthetically engineered dermal substitute is MatriDerm® (MedSkin Solutions Dr. Suwelack), a bovine-derived collagen matrix with noncross-linked collagen fibers of types I, III, and V matrix coated with elastin fibers. Synthetic dermal substitutes such as Integra® and MatriDerm® are permanent dermal regenerative templates that will be ultimately covered by an epidermal autologous graft. For temporal coverage of large wounds, dermal allografts or xenografts are available (see Table 15.3). Allografts and xenografts will be rejected by the recipient and may adhere in patients with large burn injuries for several weeks because of the post-traumatic immunosuppressed stage. After 2–3 weeks dermal

dressings will be removed and a well-vascularized wound bed is found underneath that is ready for final skin reconstruction by autologous grafts. Infection of the acellular dermis demands careful wound dressing and infection control. Another drawback for human- and porcine-derived dermis is possible viral infection transmission.⁵⁵

Cell cultures

Epithelial cell culture autografts were first introduced by Rheinwald and Green in 1975 and pose a milestone in skin regeneration.⁵⁶ In patients with extensive burns, donor sites are often limited. Cultured epithelial autografts (CEA) are keratinocytes harvested from a small biopsy of the same patient that are then expanded manifold in the laboratory (Fig. 15.16).

The time needed to expand keratinocyte cultures *in vitro* for clinical use is dependent upon the delivery method. In order to obtain sheets of confluent keratinocytes as in normal epidermis, it may take up to 5 weeks. This time can be shortened to less than 2 weeks⁵⁷ by expanding the cultures on bioscaffolds that allow cell attachment and proliferation prior to transplantation. Hyaluronan or collagen scaffolds have been demonstrated to be very useful in delivering cell-seeded sheets with approximately 80% confluence up to even multi-layered epithelial tissue constructs. Cell suspensions have the advantage of being delivered faster, reducing the *in vitro* time to only 5–7 days. Recently, ReCell® (Avita Medical), invented

Fig. 15.15 Skin regeneration with dermal substitutes. If large, deep skin defects have to be covered with thin split-thickness skin grafts, dermal substitutes can be used to augment the dermal layer and therefore the aesthetic and functional outcome. (Adapted from www.integra-ls.com.)

by Fiona Wood *et al.*, introduced an even faster method, applying noncultured keratinocytes in a one-step procedure.⁵⁸ Since in deep wounds time is a critical issue, this strategy, offering accelerated delivery, is promising, although still poorly characterized. One major concern is whether cells directly sprayed on the wound surface are able to find attachment sites to engraft and survive. Another bedside approach for epidermal graft is represented by the Cellutome™ (KCI, TX), which allows for harvesting epidermal islets down to the basal layer. The islets are then transferred on the recipient wound via a dressing and the donor site heals spontaneously in a few days.

The introduction of CEA in clinical practice dates back more than 20 years, but the best delivery method, as well as

efficacy and indications, has not been identified yet. Published studies have reported take rates of CEA on biomaterials varying from 0 to 80%, raising many questions about their effectiveness. Boyce *et al.*⁵⁹ described bilayered autologous skin constructs with keratinocytes and fibroblasts on collagen-glycosaminoglycan matrixes that showed promising results in burn treatment. Direct comparison of autologous bilayered skin constructs versus STSGs showed higher initial nontake rates and regraftment after treatment with the skin construct, while STSG-treated areas healed spontaneously. Once wound closure occurred, the outcomes showed similar results in skin quality at longer time points. The variability may be explained by heterogeneous wound cohorts, inconsistencies in the time at which wounds were analyzed, treatment techniques, and measuring systems.

Bioengineered cultured allogeneic bilayered constructs

Cell-seeded skin constructs were first described in the early 1980s, when autologous keratinocytes and fibroblasts were

Fig. 15.16 Keratinocyte cultures. Epidermal cells can be harvested from a small biopsy from the patient and expanded manifold *in vitro*. Once the expansion is achieved the autologous keratinocytes can be delivered back to the patient. (Adapted from *Autologous Cultured Epidermis*, www.jpte.co.jp.)

seeded into collagen glycosaminoglycan matrixes by centrifugation.⁶⁰ Further research found neonatal skin cells to be very efficient in accelerating wound healing. Neonatal foreskin keratinocytes and fibroblasts were then used in combination with biological or synthetically engineered scaffolds to stimulate wound healing in topically applied allogeneic skin constructs. Other than autologous cells, which seem to integrate into wound tissues, allogeneic constructs rather stimulate healing by growth factor release and initial production of extracellular matrix proteins, but are rejected eventually. Apligraf® (Organogenesis, Canton, MA and Novartis Pharmaceuticals, East Hanover, NJ) is a bilayered living skin equivalent composed of type I bovine collagen and allogeneic

keratinocytes and fibroblasts obtained from neonatal foreskin. Fibroblasts are cultured in the collagen matrix where they proliferate and augment the extracellular matrix with all types of proteins. Keratinocytes are then added and build up the epidermal layer. The living skin construct supports skin graft take in difficult wounds, such as burn wounds, or accelerates healing in chronic wounds. With a shelf-life of 5 days at room temperature, Apligraf® has to be applied fresh either as a temporary dressing or over meshed STSGs.

Future products that are less immunogenic might be useful for improving skin regeneration, and novel technologies such as 3D printing will soon make clinically available more sophisticated synthetic constructs.

Tissue engineering

Andrea J. O'Connor, Diego Marre, Kiryu K. Yap, Daniel E. Heath, and Wayne A. Morrison

SYNOPSIS

- Tissue engineering, i.e., a growth of three-dimensional (3D) tissues using cells, scaffolds, and blood supply, calls on the skills and expertise of cell biologists, engineers, and clinical surgeons.
- It aims to replicate the embryological process of tissue regeneration rather than adult healing and, given the complexity of the process, much of our effort to date may seem simplistic.
- Nevertheless, much progress has been made across the full spectrum of the research field. This chapter outlines the historical beginnings of tissue engineering and discusses the current status, addressing the three structural components of tissue: cells, matrix, and vascular supply.
- Biomaterials science and applications are discussed as well as an overview of emerging technologies in the field.
- Much of the work in tissue engineering has been performed *ex vivo* and unfortunately many of these experiments do not predict the fate of cells and matrices *in vivo*.
- Models of *in vivo* tissue engineering are discussed along with the progress in specific fields.
- Very few clinical trials have been undertaken, controls or placebo groups are difficult to incorporate in trial design, and tracking the fate of implanted cells is difficult in humans.
- All this needs to be viewed with the perspective that, to date, very few truly tissue-engineered products have come to market despite huge expectations and investments.

Introduction

Traditional reconstructive plastic surgery techniques “rob Peter to pay Paul”. The long-held hope for the ultimate reconstruction has been allotransplantation but to date drug morbidity makes the risk-benefit ratio unfavorable for non-vital organs except in rare circumstances. Tissue engineering has emerged as a possible new direction where ideally our own body is stimulated to generate its own replacement tissue.

Definition of tissue engineering

The definition of tissue engineering quoted by most authors is that it is “an interdisciplinary field that applies the principles of engineering and the life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function”.¹ It stressed the key roles of engineering techniques, material science, biochemical expertise, and cell biology. What it did not stress was the role that blood supply would play if and when such engineered tissues were to be transplanted into the body. It is to this piece of the tissue-engineering puzzle that plastic surgeons may hold the key and why the clinical application of tissue engineering will become the province of the plastic surgeon.

Regenerative medicine

While tissue engineering has predominantly surgical roots with research directed by cell biologists and engineers, regenerative medicine, a modernized branding for cellular therapy, was the province of physicians and cell biologists. It has since expanded to target organ regeneration and there is now considerable crosstalk between the disciplines. For the purpose of this chapter, we distinguish tissue engineering as the pursuit of 3D structural tissue generation.

The classical paradigm of tissue engineering followed Jack Burke’s artificial dermis skin model of seeding cells on to a biodegradable matrix scaffold and implanting it into a vascularized bed.² This would rapidly nourish the graft and, by a combination of survival of implanted cells and substitution, the “new skin” would become functional. Clinical needs for bone and cartilage determined early research directions and this gave pre-eminence to the engineering materials side of the tissue-engineering pendulum as structural load, stability and ideally biodegradability were clearly essential. The spectacular image of the “human ear” in the mouse (Fig. 16.1) galvanized scientists and the public alike as to the potential offered by tissue engineering and reinforced the dogma of expanding cells in culture, seeding them *ex vivo* into scaffold

Fig. 16.1 “Human ear in the mouse”: cultured bovine cartilage cells seeded on a PLGA scaffold in the shape of a human ear and implanted in the back of a mouse. (Reproduced from Cao Y, Vacanti J, Paige K, et al. *Transplantation of chondrocytes utilizing a polymer-cell construct to produce tissue-engineered cartilage in the shape of a human ear*. *Plast Reconstr Surg*. 1997;100:297–302.)

matrix and implanting the composite into the body.³ The journal *Tissue Engineering* was established in 1996 and many publications focused on novel synthetic biomaterials attempting to replicate pore size and connectivity of nature’s extracellular matrix (ECM) using sophisticated machinery and mathematical modeling. Toxicity, structural integrity, biodegradability, surface modifications, cell survival, adherence, migration, and proliferation could all be tested in *ex vivo* models. Bioreactors could greatly expand cell numbers and mimic *in vivo* physical environments to allow more sophisticated *ex vivo* experimentation.

The *ex vivo* paradigm stumbled when attempts were made to translate advances into the living animal. Biomaterials proved toxic to cells in some cases and acted as foreign bodies.⁴ Their dynamic structural behavior was very different to *ex vivo* testing and cells found life hostile in the new world. Despite the obvious need for multidisciplinary cooperation, most early research was directed in isolation and this has led to delayed progress in tissue engineering. The engineer’s mindset is focused on scaffold structure, tensile strength, biocompatibility, and surface modification while the cell biologist’s is on cell identification, expansion, and differentiation. Scaffold modeling was based on sophisticated replication of human ECMs with respect to pore size, but evaluation was largely done *in vitro*. Both teams are laboratory-based, observing cell responses outside the living animal, and had limited access to a practicing clinician’s observations, especially plastic surgeons, with respect to the behavior of foreign bodies *in vivo*. Furthermore, surgeons know from bitter experience with skin grafting that cells seeded on to an implanted scaffold *ex vivo* and then implanted are unlikely to connect to a blood supply in sufficient time to avoid ischemic death. Vascularization is vital to cell survival and is a key to any successful multidisciplinary partnership towards clinical translation of tissue engineering. Unfortunately, early tissue engineers were beguiled by selecting tissues that were very thin, such as skin, which could rapidly connect to a blood supply or tissue that did not need a blood supply, namely cartilage. Once 3D soft tissues were attempted, it became evident that cell survival was poor and that blood supply was paramount.^{5–7}

Embryology

Tissue engineering at its core is an attempt to replicate embryology or fetal healing. Here, new tissues form in response to certain signals, both biochemical and biomechanical.⁸ The tissues are determined or patterned according to a genetically guided time sequence where growth factors and their chemical gradients as well as changing physical forces in the matrix attract, guide, and differentiate primitive cells into functional clusters. In this process, cells will link with a capillary bed, lay down their own matrix, and create an environment appropriate to their expansion and development. This relatively new concept of “self-assembly” is important to appreciate when translating embryogenesis into a model for tissue engineering. As cells change their phenotype, for example, from precursor to differentiated or from motile and proliferative to resting and clustered, their ECM requirements alter accordingly. Many cells secrete their own matrix suitable to their needs. This constant change cannot easily be replicated in the laboratory and it is simplistic to believe we can seed cells on to one specific matrix and assume this will be appropriate for the cells’ needs throughout their development *in vivo*, nor is it easily conceivable that “smart surfaces” can be imprinted on synthetic matrices in layers programmed to be released according to the changing cells’ needs when at this point we do not know what these needs are.

Examples from nature

Nature has given us many examples of spontaneous tissue regeneration or engineering which give clues to how this might be modeled artificially. The liver has been known since ancient times to self-regenerate and is captured in the legend of Prometheus, a Titan, who stole fire from Zeus and gave it to mortals. As punishment, he was bound to a rock while a great eagle ate his liver each day, only to have it grow back to be eaten again.

A salamander regrows its legs, the fetus repairs wounds with minimal scarring, and humans have the capacity to gain and lose adiposity rapidly. Ruptured tendons can regenerate across gaps when their ends are retained within their synovial sheath where their matrix and cellular environment are maintained and axial mechanical force signals are transduced into biochemical stimulation (Fig. 16.2). Muscles also will regenerate across gaps in the same way.

Access the Historical Perspective section, including Fig. 16.3, online at <http://www.expertconsult.com>

Components of tissue engineering

Adult wound healing involves deliberate sloughing of damaged tissue and repair by rapid wound closure, scar, and contracture. A primary goal of tissue engineering is to achieve a more scarless regeneration through the use of stem cells, matrix, and growth factors delivered according to a sequence and type learned from embryology, as described above.

Simplistically, our tissues can be viewed as a composite of: (1) cells (both parenchymal and stromal); (2) matrix; and (3) blood vessels. Each of these components must be considered

Historical perspective

The term “tissue engineering” was coined at a meeting sponsored by the National Science Foundation in 1987. Implied in the definition of tissue engineering is the use of living cells, biomolecules, and/or biomaterials.⁹ One of the earliest human applications of the concepts of tissue engineering is in oral surgery with what is termed “guided bone regeneration” (GBR) or guided tissue regeneration (GTR).¹⁰ This surgical procedure utilizes barrier membranes to direct growth of bone and soft tissue and is predominantly applied in the oral cavity to support new bone growth on alveolar ridges to allow stable insertion of implants.¹¹ The membrane which is inserted under the mucoperiosteum creates a dedicated space that collects the raw ingredients of osteogenesis – periosteal and bone-derived osteoblasts, vascular cells, tissue fluid, and matrix secretions appropriate for the biochemical signaling of bone formation. The rigid surface of a membrane induces biomechanical signals to the cells to proliferate and migrate along its surface. Platelet-enriched plasma is sometimes added to enhance tissue growth by augmenting the growth factor profile.¹²

Similar phenomena are observed with “distraction osteogenesis”, where long bones are osteotomized within their periosteal sleeve and slowly distracted (Fig. 16.3). The

expanding space spontaneously fills with new bone. Just as in GBR, the environment within the newly created space is exclusively conducive to bone formation. Both GBR and distraction osteogenesis are examples of what would now be called endogenous or intrinsic tissue engineering, where the body grows its own tissue in response to local signals of trauma, ischemia, inflammation, and mechanical forces which promote vascularization followed by specialized tissue regeneration.

Cancellous bone grafting, first described by the New Zealand plastic surgeon Rainsford Mowlem,¹³ is an even earlier example of a tissue-engineering concept, in this case using the extrinsic principle where a scaffold loaded with cells is implanted into a new site. Most of the cells probably die but the bone matrix survives and acts as a scaffold with the appropriate signals to attract new blood vessel and bone-forming cells into its interstices and replace it by “creeping substitution”. The bone remodels according to the biomechanical forces of its new environment, as articulated by Wolf’s law. Bone regeneration has also been encouraged by the implantation of synthetic porous scaffold materials such as Proplast and more recently MEDPOR, usually primed with autologous blood to attract ingrowth of endogenous tissue.

As stated previously, tissue engineering and regenerative medicine are conceptually different but both disciplines now borrow from each other’s progress.

Fig. 16.3 (A) Thumb stump with distraction device. (B) X-ray of bone distraction. (C) New bone filling the gap.

Fig. 16.2 Spontaneous regeneration of ruptured extensor digiti minimi tendon at the wrist (lower tendon held with forceps).

in the context of tissue engineering as cell maintenance and behavior including growth and regeneration are influenced by biochemical and biomechanical interplay. Furthermore, the development of a functional tissue must be vascularized to ensure survival of the neotissue. Each of these components is the purview of the tissue engineer.

Cell sources for tissue engineering

Cells used for tissue engineering may be autologous, heterologous, or xenogeneic and each type may be mature differentiated or in precursor stem cell form. Ideally, cells for tissue engineering should be our own cells, and endogenously mobilized to participate in the regenerative process, thereby avoiding issues of rejection and *ex vivo* cell processing or manipulation. This is in essence wound healing, where key cells, both local and distant, are mobilized in response to biochemical gradients and biomechanical forces. Although this endogenous repair is ideal it is, unfortunately, not often realized.

Instead, early tissue engineering strategies relied on the collection of the cell type of interest from the patient, *ex vivo* cell expansion, and then reimplantation into the patient, usually in conjunction with a tissue engineering scaffold support. Many cell types such as chondrocytes for cartilage, osteocytes for bone, Schwann cells for nerves, and fibroblasts for ligament and tendon engineering are highly proliferative in culture and were early tissue engineering candidates. All these cells have significant proliferative potential *in vitro* but, once implanted, assuming they survive, are not expected to expand further. However, other differentiated cells such as adult cardiomyocytes, hepatocytes, and adipocytes are infamously difficult to culture and expand *in vitro*, significantly limiting the application of this tissue engineering approach. A second challenge with this early model of tissue engineering is that collection of the patient's primary cells requires biopsy of the patient's tissue which is, at best, uncomfortable and, at worst, impossible due to the diseased state of the tissue.

To circumvent these roadblocks, today's tissue engineers will more likely utilize stem cells that can be expanded and differentiated *ex vivo*. There are multiple types of stem cells that have been explored including embryonic, adult, and

induced pluripotent stem cells. Here we will discuss embryonic stem cells and then focus on stem cell types most relevant to the plastic surgeon, the sources of cells, their advantages and disadvantages and briefly discuss their use in tissue engineering.

Embryonic stem (ES) cells

Embryonic stem (ES) cells are totipotent, infinitely proliferative, and can be differentiated into all tissue types. However, they are also unstable and form teratomas. Additionally, their sourcing and utilization are limited by ethical/legal concerns. Successful differentiation protocols have been found to induce ES cells along specific lineage pathways from all germ layers towards many specific tissues and organs.¹⁴ These cells are probably immunogenic and ethical issues will persist. There are many regulatory and organizational issues that will make pathways into the clinic difficult for elective procedures such as tissue engineering, especially proving that they will not form cancer.

Adult stem cells

Adult stem cells are multipotent and limited in their proliferation capacity and differentiation potential. They are collected and expanded from tissue biopsies through variations on a process referred to as the colony forming unit (CFU) assay.¹⁵ These progenitor cells are present at low frequencies in the patient samples, often approximately 1 progenitor cell/100 000 nucleated cells (though the prevalence of adipose-derived stem cells is significantly higher). The tissue sample is processed to remove some of the contaminating cells, and the remaining mononuclear cells are then plated onto tissue culture plastic. The progenitor cells are then isolated and purified by their ability to adhere to the substrate and proliferate. Non-adherent cells are removed and the medium is supplemented with factors that promote the survival and growth of the cells of interest. Over two to three passages the experimenter is left with a relatively pure population of stem cells.

Two of the first documented adult stem cells were both found in bone marrow: (1) hematopoietic stem cells (HSCs), which differentiated into the white blood cell population and (2) mesenchymal stem cells (MSCs), the progenitors of bone, cartilage, fat, and muscle.^{16,17} Additionally, endothelial progenitor cells (EPCs) have been isolated and cultured from adult peripheral blood.¹⁸ Furthermore, MSCs and EPCs are now known to be present not only in bone marrow but also in fat tissue associated with the microvasculature,¹⁹ where they are known as adipose-derived stem cells (ASCs). In more recent years, tissue-specific stem cells have now been isolated from almost every organ as well as mesenchyme and include cardiac, liver, lung, kidney, brain, breast and others. Here we focus on the adult stem cells that are of most use to the plastic surgeon: the mesenchymal stem cell, the adipose-derived stem cell and the endothelial progenitor cell.

Mesenchymal stem cells

Classically, MSCs were derived from bone marrow and used as connective tissue progenitors (cartilage, bone, fat, and muscle). MSCs have the advantage that they do not express MHC class II markers and several studies have suggested they are relatively immune-privileged and may be used as

allografts. This is a potentially attractive concept where cells could be sourced from stem cell banks for tissue engineering.^{14,20} Due to these attractive properties, MSCs have become a favored source of cells for the engineering of mesenchymal tissues, the main building blocks employed for plastic and orthopedic reconstruction.

Due to their immune-privileged status, many researchers are attempting to expand upon the utility of MSCs. One avenue of research is differentiating these cells into cell types that originate from different germ layers. Furthermore, researchers have searched for MSCs in other more readily accessed tissues that can be isolated through less invasive means. Mesenchymal stem cell-like cells have been observed in a variety of tissues including skin, muscle, umbilical cord, placenta, corneal stroma, and dental pulp of deciduous teeth. However, all of these sources produce progenitor populations with nuanced differences in their proliferation and differentiation potential with bone marrow-derived MSCs remaining the most understood of MSC-like cells available.

MSCs injected as a form of cellular therapy have been widely explored for a variety of conditions including cardiac disease, peripheral vascular disease, and irradiation injury in humans. Additionally, a large amount of experience in the horseracing industry boasts survival, differentiation, and function of such cells. However, few of these studies were controlled and tracking of cells was absent or difficult to assess. With the exception of brain, almost no cases could confirm that the MSCs survived in significant numbers or that these survivors differentiated into the injured tissue type. Interestingly, there is a growing body of knowledge that suggests MSCs injected as a form of therapy do not aid recovery through direct incorporation with damaged tissue. Most studies now concede that the paracrine-growth factor-hormonal-cytokine immune-modulatory effects probably account for the benefits seen with these stem cells. For example, ischemia increases homing of these cells to the injured site where MSCs release high levels of vascular endothelial growth factor (VEGF) to modulate the repair of capillaries. Additionally, MSCs injected intravenously in cardiac infarct models do not implant in the heart nor become heart tissue but lodge in the lung, where they are activated to secrete the anti-inflammatory protein TSG-6,²¹ and it is probably the anti-inflammatory factor that induces the beneficial effects. More recently, MSCs have been used as intravenous infusions for the treatment of multiple sclerosis, with promising results. It is felt that the response was anti-inflammatory in nature due to the release of high numbers of M2 anti-inflammatory macrophages.²² Despite the clear evidence that these cells can be used in beneficial cellular therapies, the exact mechanism of action and the best method of employing the cells are still unclear. However, the clinical use of these cells will continue to increase. In fact, the National Institutes of Health of the United States has created a bone marrow stromal cell transplantation program prepared from bone marrow of healthy subjects to treat patients with inflammatory bowel disease, cardiovascular disease, and acute graft-vs-host disease.²³

Adipose-derived stem cells

Due to their abundance and ease of harvest by liposuction, adipose-derived stem cells are a preferred autologous stem cell source. This cell type has similar properties to bone marrow-derived stem cells but is more abundant, more easily

cultured, grows more rapidly and can be cultured for longer periods than bone marrow stem cells before senescence. While bone marrow-derived mesenchymal stem cells are present at extremely low frequencies, one gram of adipose tissue can yield 5000 stem cells making fat a much richer source of stem cells than bone marrow.²⁴ Additionally, some studies have illustrated that the ASC population may also have low immunogenicity.^{25,26} Interestingly, the ASCs are not thought to be a pure cell population, and for tissue-engineering and fat injection purposes, it is clear that obsessive attempts to isolate the “pure ASC” may be counterproductive as the other cells, especially the EPCs, may also contribute to the apparent functional effects of stem cells.

As with MSCs, cellular therapies utilizing ASCs have shown promising results. Partially purified ASCs which still retain CD34 and CD90 markers grown into spheroid clusters in a gel culture system differentiate into endothelial cells and capillary structures in methyl cellulose and these produce high levels of VEGF. They also rapidly differentiate into adipocytes in adipogenic media, making them potentially suitable for adipose tissue engineering.²⁷ Other growth factors released from ASCs include macrophage colony-stimulating factor, GM-CSF, VEGF, anti-apoptotic factors, hepatocyte growth factor, and transforming growth factor- β (TGF- β). In hypoxia, the VEGF levels are significantly increased, leading to angiogenesis and decreased apoptosis.

Endothelial progenitor cells

A major requirement in tissue engineering is the incorporation of a functional vasculature network in the neotissue. One cell type that shows promise in this arena is the endothelial progenitor cell (EPC). These cells were first identified in 1997 by Asahara *et al.*,²⁸ are present in adult circulation, and autologous cells can be isolated and expanded from peripheral blood collected through simple venipuncture. Subsequent research has illustrated there are actually two distinct EPC populations that participate in vascular repair and angiogenesis via different mechanisms. The first population, referred to as circulating angiogenic cells (or colony forming unit–Hill cells) are not believed to directly incorporate into the endothelium; instead, they are posited to support resident endothelial cells through paracrine signalling. Endothelial colony forming cells (ECFCs), on the other hand, have been shown to differentiate into cells with endothelial phenotype and to regenerate an endothelial cell population.¹⁸ Both cell types can be used to promote autologous endothelialization.

Challenges associated with adult stem cells

Adult stem cells are advantageous in tissue engineering as they provide an autologous and/or non-immunogenic source of cells. However, they are not without limitations. Adult stem cells display patient-to-patient variations in their prevalence, proliferative capacity, and differentiation potential.^{29–31} Additionally, their utility is also a factor of age and disease state of the donor. Furthermore, during *ex vivo* expansion, cells may exit the cell proliferation cycle (prematurely senesce) or prematurely lose differentiation potential.^{32,33}

Induced pluripotent stem cells

One of the most exciting discoveries in stem cell science occurred in 2006 when Takahashi *et al.*³⁴ described a method

of converting murine somatic fully differentiated skin cells, mostly fibroblasts, to an embryonic-like state using four transcription factors. The achievement was then repeated in 2007 for human cells. They are termed induced pluripotent stem (iPS) cells and possess unlimited proliferation capacity and the ability to differentiate into cells from all germ layers both *in vitro* and *in vivo*. Additionally, these cells can be patient-specific, thus present no issues of allogenicity and they are not encumbered by the same legal/ethical concerns as embryonic stem cells. In 2012, human iPS cells were even produced from exfoliated epithelial cells present in urine.³⁵ The major problem associated with the production of iPS cells is that it requires genetic manipulation of the cells. Furthermore, two of the genes used in this process (c-Myc and KLF4) are oncogenes.

Much of the research related to iPS cells in recent years has revolved around improving safety. Specifically, inducing a pluripotent state without genetic modification has been a major goal. Zhou *et al.* accomplished this task in 2009 by delivering the four proteins that the above-mentioned genes code for directly into the cell. Generation of these cells, referred to as protein-induced pluripotent stem cells (piPSCs), bypasses the need for viral or plasmid transfection and reduces the risks of cancer formation.³⁶ A current drawback to this technique is that the efficiency of the protein induction is very low, and research is addressing this limitation. Mice have been cloned from safer versions of their own iPS cells by implantation into an enucleated ovum, and these animals have reproduced and no cancers have been detected.³⁷ Another technological challenge for the utilization of iPS cell technology is that these cells are not immune privileged requiring collection, induction, expansion, and differentiation of autologous cells. This is a costly and time-consuming scenario. The alternative to using autologous cells is to create a bank of iPS cells that can be HLA matched to the patient. Clinical utilization of these cells is being explored. Beyond the realm of tissue engineering, models based on these cells have also become powerful tools for drug discovery and investigations into genetically based diseases.

Cellular interactions with their environment

Many cell types are exquisitely sensitive to stimuli present in the environment. These stimuli are diverse and include soluble molecules, molecular recognition sites present in the solid phase (ECM or biomaterial), interactions with other cells, substrate stiffness and the micro/nano-structure of the surroundings. In this section we consider how these parameters can affect the phenotype and behavior of cells and in the biomaterials section we discuss how this knowledge can be translated into next generation materials for use in tissue engineering.

Soluble signals

Many soluble biomolecules such as metalloproteins, growth factors, and chemokines play vital roles locally and systemically in repair and tissue development. Starting from the earliest stages of life, embryogenesis is critically dependent on growth factor cascades released sequentially according to a genetic code and time clock. In adults these cellular signaling molecules continue to play crucial roles. For example,

inflammatory cytokines and local angiogenic growth factors stimulate endothelial cell migration, proliferation, and mitogenesis and growth factor cytokines signal distant precursor cells, including EPCs.^{10,38} This knowledge has direct impact on the field of tissue engineering, as it is necessary to know the appropriate soluble signaling molecules to maintain cell viability both during culture and *in vivo*, to maintain cellular phenotype, and to drive lineage specific differentiation of stem cells. However, biomolecules such as growth factors are expensive, have short half-lives and angiogenic growth factors have the particular risk of reactivating dormant cancer when used for post-cancer resection reconstruction. The need for local delivery of specific biomolecules at specific concentrations is key to successful tissue regeneration and will be discussed below via biomaterials with controlled release properties.

Matrix signals

In addition to surface receptors that engage with soluble factors, cells also possess receptors such as integrins and syndecans that bind to a variety of ligands present in the extracellular matrix (ECM). Many cell types are adhesion dependent, meaning that if they do not experience biologically specific binding to an external matrix they will not maintain viability. Additionally, the number and strength of bonds with the external matrix affects a wide variety of cellular behaviors ranging from adhesion, focal adhesion formation and migration to morphology. Additionally, the ECM binds and sequesters growth factors that also drive cellular function. Knowledge of the biologically specific binding that occurs between cells and their matrix has resulted in the development of biofunctionalized materials that can promote specific cell functions.

Intercellular signals

Cells also interact with neighboring cells in both native tissue and in *ex vivo* culture. These interactions can occur through two main methods: direct contact via receptors such as cadherins and soluble signaling through paracrine factors. In traditional cell culture, single populations of cells are grown in isolation, implanted and rely on recruitment of supporting cellular structures and matrix to evolve into a stable, functional tissue. However, co-culturing cells with other types prior to implantation can facilitate their survival and function, such as endothelial cells for vasculature,³⁹ MSCs for paracrine effects or for their ability to incorporate into developing tissues *in vivo* like blood vessels¹⁹ and beating cardiomyocytes with ASCs *in vitro* to initiate differentiation into cardiac lineage.⁴⁰

Mechanics and structure of the environment

In addition to biological signaling that arises directly from a receptor binding to a ligand, cells also respond to the mechanical properties and dimensionality of their environment. The cell measures the flexibility of its substrate cytoskeleton myosin push/pull on the focal adhesion. The response then leads to changes in tyrosine phosphorylation to signal transduction to the nucleus. *In vivo*, this phenomenon is commonly observed during events such as embryonic development and wound healing⁴¹ as synthesis/degradation of ECM proteins,

movement of cells, or fluid shear from blood flow modulate the mechanical properties of the cells' environment.

The mechanical properties of tissues and their components vary widely (Table 16.1 and Fig. 16.4A) and so the physical microenvironment of particular cells *in vivo* also varies significantly. In traditional cell culture, cells are grown on rigid and two-dimensional tissue culture plastic, the equivalent of cells being firmly stretched in clinical situations. They then move, migrate, and proliferate until they reach confluence. The same cells when placed in a soft 3D culture gel environment sense a modulus that encourages the cells to cluster together into spheroids (Fig. 16.5). When the cells pull on the soft matrix they pull it into a ball, stop dividing, and many apoptose. If they are stem cells the stiffness of the environment may promote lineage-specific differentiation.^{42–44} Engler *et al.*^{44,45} have shown that MSC lineage specification can be altered *in vitro* when cells are cultured on substrates of different stiffness (see Fig. 16.4). Cellular morphology, gene expression, migration, and proliferation are also modulated by the mechanical properties of their microenvironment.^{43,46–48}

The response of cells to environmental stiffness and dimensionality provides the tissue engineer with an additional tool that can be used to direct cell function. For example, chondrocytes change morphology and lose their chondrogenic capacity in 2D monolayer culture but can maintain these features in 3D culture.⁴⁹ The response of cells to mechanical stimulation is used in tissue engineering strategies such as distraction osteogenesis. Periods of stretch promote proliferation and migration while relaxation incites cells to cluster together and terminally differentiate into bone. Guided tissue regeneration similarly works by presenting the cells with a hard surface that stimulates them to divide and to migrate.

Stem cell mechanobiology is attracting increased attention as understanding develops of the influence of substrate mechanics and architecture on differentiation.⁴⁵ Cells may be cultured in 3D on biomaterial supports such as porous scaffolds, hydrogels, or microspheres under conditions designed for the desired cell attachment, migration, proliferation, and differentiation.^{50,51} This knowledge can influence the development of new biomaterials with tailored properties and direct the fabrication of these materials into three-dimensional scaffolds to maximize the healing process.

Fig. 16.4 Effects of substrate mechanical properties on differentiation. **(A)** Range of microenvironment elasticity for various solid tissues. **(B)** Mesenchymal stem cells (MSCs) grown on collagen I-coated hydrogels of various elastic moduli differentiate to phenotypes corresponding to tissues of the same elasticity as the hydrogels. (Adapted From Engler AJ, Sen S, Sweeney HL, et al. *Matrix elasticity directs stem cell lineage specification*. Cell. 2006;126:677–689.)

Table 16.1 Typical mechanical properties of selected tissues and tissue components

Material	Elastic modulus	Yield stress	Maximum strain
Elastin	100kPa	300 kPa	300%
Cartilage	10 MPa	8–20 MPa	70–200%
Skin	35 MPa	15 MPa	100%
Muscle fascia	350 MPa	15 MPa	170%
Tendon	700 MPa	60 MPa	10%
Cortical bone	17.4 GPa	160 MPa	1.8%

Biomaterials used in tissue engineering

In addition to cells, a main component of solid tissues is the extracellular matrix which provides structure and biochemical signals to the cells. However, when cells are expanded outside the body, they typically grow in monolayers, not the intricate patterns of a fully realized three-dimensional tissue. Therefore, cells are often seeded onto a 3D scaffold. In this light, biomaterial scaffolds can be thought of as artificial ECMs. Here we discuss the main classes of biomaterials for tissue engineering and methods employed to create materials that drive desired cellular behaviors.

Many criteria exist for biomaterials to be suitable for tissue engineering applications, as outlined in Box 16.1. A wide

Fig. 16.5 (A) Preadipocytes growing on two-dimensional tissue culture plastic. (B) The same cells growing in three-dimensional gel culture form spheroids. (Reproduced from Stillaert FB, Abberton KM, Keramidaris E, et al. *Intrinsics and dynamics of fat grafts: an in vitro study*. *Plast Reconstr Surg*. 2010;126: 1155–1162.)

variety of synthetic and naturally derived biomaterials have been considered to meet these needs although they do not generally ideally satisfy all of these criteria.⁵² Early tissue-engineering attempts tended to utilize materials that had already been used in other clinical applications, such as the polymers used in degradable sutures, or natural materials such as coral, alginate and collagen. More recently, numerous alternatives have been formulated as researchers aim to develop multifunctional biomimetic biomaterials to suit the specific demands of tissue engineering, which can differ significantly from those of other biomaterial applications. New materials require extensive testing *in vitro* and *in vivo* before

BOX 16.1 Criteria for biomaterials to be suitable for tissue engineering applications

Biocompatibility, i.e., eliciting a suitable host response in the specific application. Suitable mechanical properties for target tissue and implantation site.

Biodegradability over desired timeframe with suitable mechanical properties and non-harmful degradation products.

Not containing harmful impurities.

A host response *in vivo* that does not prevent desired tissue development; i.e., inflammation and foreign-body response are not excessive.

Ability to be fabricated into desired structures.

Cost-effective.

Ability to be sterilized without harmful changes to their chemical or physical properties.

Adequate stability and shelf-life.

Ability to promote desired cellular responses, e.g., proliferation, differentiation, gene expression.

clinical acceptance, with very high costs and relatively low rates of translation from the laboratory to the clinic.⁵³ Despite this, much research continues and a range of such materials are in this testing pipeline.

Biomaterials for tissue engineering may be naturally occurring in the human body or derived from other natural or synthetic sources. They may be ceramics, polymers, hydrogels, or composites of these. Decellularized tissues are also used as biomaterials to support tissue growth. The physical form of biomaterials for tissue-engineering applications can also vary to suit the application – solid materials, porous scaffolds, microspheres, hydrogels, injectable materials that may cross-link *in situ*, or other configurations can be fabricated. Whilst it may be feasible to produce complex biomimetic materials to influence cell fate *ex vivo*, simplicity is also desirable to facilitate regulatory approval and translation of new materials into clinical application.⁵⁴ Selection of biomaterials will depend on the specific requirements of the tissue being targeted.

Biodegradable materials

Most biomaterials used in tissue engineering applications are biodegradable so that, over time, the material will disappear at a specified rate and be replaced by neotissue. The rate of degradation can vary widely so the mechanical integrity may be retained for as little as days or weeks, or as long as a year or more. The rate of degradation and loss of integrity will depend on the type of biomaterial, the site of implantation, properties of the biomaterial construct such as surface area to volume ratio, size, and surface chemistry. Fig. 16.6 shows examples of the loss of mechanical strength of biodegradable polymers.

As these materials degrade over time, one of the major challenges with biomaterial design is the prevention of sudden loss of physical integrity. Additionally, rapid degradation may lead to excessive concentrations of the degradation products of a biomaterial that can cause adverse tissue reactions. This

Fig. 16.6 Changes in tensile strength of biodegradable polymers during degradation *in vitro*. (Reproduced from Suzuki M, Ikada Y. *Biodegradable polymers in medicine*. In: Reis RL, Román JS (eds). *Biodegradable Systems in Tissue Engineering and Regenerative Medicine*. Boca Raton: CRC Press, 2005.)

is well known for the polylactides and polyglycolides that can undergo autocatalytic degradation with decreasing pH inside a thick-walled construct and “acid burst” leading to reduced local pH and tissue necrosis. For this reason, it is important to consider degradation rates and mechanisms in designing the composition and architecture of tissue-engineering constructs using biomaterials.

Natural biomaterials

Natural biomaterials may have the benefits of being chemically similar or identical to molecules in the body, readily degraded *in vivo*, and able to interact with cells on a molecular level. However, they can be difficult to obtain and purify, vary in properties between batches, may be difficult to sterilize, alter their properties during storage, and they may elicit significant immunogenic responses. Naturally derived biomaterials investigated for tissue engineering include proteins (e.g., collagen, gelatin, silk), polysaccharides (e.g., chitosan, hyaluronic acid), polynucleotides and extracts of ECM components.⁵⁵ These materials may be modified to tailor their properties, such as via chemical cross-linking to slow degradation and increase mechanical strength.

One natural biomaterial that is gaining increasing attention is decellularized extracellular matrix (dECM). During decellularization, cells are removed from allografts or xenografts to reduce immunogenicity but much of the complex composition and architecture of the ECM may be retained.⁵⁶ One limitation of synthetic materials is that they cannot contain the large number of biomolecules present in the ECM whilst the dECM has the potential for containing important factors, even

those that have not yet been identified. One interesting application of dECM is in the expansion of stem cells. Recently, MSCs have been cultured on dECM and the cells have illustrated significantly higher proliferation rates and maintenance of stem cell phenotype, clearly illustrating the importance of environmental control during cell culture conditions.⁵⁷

Polymeric biomaterials

Hydrophobic polymers

Numerous synthetic polymers are used in medicine and some of these are biodegradable (or bioresorbable) *in vivo*. Fig. 16.7 shows examples of the chemical structures of biodegradable polymers that could be used in tissue engineering. Among these, the polyesters poly(glycolic acid) (PGA), poly(lactic acid) (PLA) and poly(ε-caprolactone) (PCL) and their copolymers such as poly(lactide-co-glycolide) (PLGA) have been widely used in tissue-engineering approaches.⁵⁸ The mechanical strength and degradation rate of these polymers can be tuned over a wide range by changing the polymer properties (molecular weight, composition, molecular architecture, crystallinity, hydrophobicity).⁵⁹ However, many biodegradable synthetic polymers are quite hydrophobic, unlike the ECM. Exposure of such surfaces *in vivo* can lead to nonspecific adsorption of proteins of mixed orientation and states of denaturation, potentially resulting in a foreign-body reaction (FBR) to the material.⁶⁰

Hydrogels

Hydrogels are water-swollen cross-linked polymer networks which can absorb up to thousands of times their dry weight of water, which gives them the advantage of being more like most natural tissues and allowing mass transport to and from cells.⁶¹ They may be formed by physical (hydrogen bonds, ionic interactions, molecular entanglements, hydrophobic interactions) or chemical interactions (covalent bonds) and this affects their stability and degradation rates. The mechanical strength of hydrogels can be tuned within a limited range and their degradation tends to be faster than for other biomaterials. Hydrogels may be naturally derived (e.g., collagen, gelatin, hyaluronic acid, alginate) or synthetic (e.g., poly(ethylene glycol) (PEG)-based polymers).

Ceramic biomaterials

Ceramic biomaterials are primarily utilized in tissue engineering of hard tissues. Calcium phosphates, such as hydroxyapatite, and bioactive glasses have been developed as bioceramics for bone tissue engineering. Bioceramics are brittle but have high compressive strength, can bond strongly to bone, and can be osteoinductive.

Advanced biomaterials for tissue engineering

In the early days of tissue engineering, commodity materials were often used. However, these materials are often not suitable, as described above. Now we are in an exciting age of biomaterials science where materials are being designed to have tailored interactions with biology using our growing knowledge about how cells interact with their environments in order to lead to improved healing.⁶² Here we present an overview of some of these strategies and how they apply to tissue engineering.

Tailored delivery systems

As discussed above, soluble bioactive molecules play a critical role in natural tissue morphogenesis and control of their delivery both spatially and temporally to growing tissue may significantly enhance tissue-engineering outcomes. Molecules such as growth factors, anti-inflammatory peptides, and drugs may be incorporated into biomaterial delivery vehicles for release at the desired time during tissue development.^{63–65} The release systems may be designed to deliver multiple molecules over different timescales via continuous or pulsatile delivery,⁶⁶ which may be programmed or triggered by some change in the local environment.⁶⁷ Delivery systems can be fabricated from biodegradable polymers in the form of micro- or nanoparticles or capsules, or incorporated into other

biomaterial constructs such as within the walls or on the surfaces of scaffolds or hydrogels.⁴⁷ It is critical to the design of an effective delivery system that the payload of bioactive molecules retains its conformation and bioactivity throughout the loading and release processes. An additional challenge is the prediction of release rates *in vivo*, which generally differ significantly from those *in vitro*.

Controlled delivery of growth factors is desirable as they have short half-lives *in vivo*, are relatively slow to diffuse due to their size, and may have undesired effects if delivered systemically.⁴⁶ The potential benefits of growth factor delivery on adipose tissue engineering were demonstrated *in vivo* using gelatin microspheres to deliver fibroblast growth factor-2 (FGF-2) over an extended time in a mouse tissue-engineering chamber.⁶⁸ Chambers containing an autologous

fat graft and gelatin microspheres loaded with FGF-2 grew significantly more tissue than controls with free FGF-2 or blank microspheres (Fig. 16.8).

Similar approaches are also being investigated for cell delivery, wherein cells may be loaded onto degradable microspheres *in vitro*, allowed to attach, migrate, and proliferate on or within the spheres and then delivered to a target site for tissue growth. This significantly increases the surface area available for attachment of adherent cells and using biodegradable beads that can be delivered *in vivo* avoids the need to detach the cells from the culture surface for delivery.⁶⁹ It has been shown that ASCs loaded into chitosan microspheres were viable and maintained their multipotency after *in vitro* culture.⁷⁰

Smart polymers

Changes in environmental conditions can result in changes to the molecular conformation of many materials. These environmentally-induced changes may be harnessed, resulting in so-called smart polymers (Fig. 16.9). These types of change can be used to encapsulate and release payloads of cells or drugs, to form gels upon injection *in vivo*, or for cell sheet engineering.^{60,71,72} A classic example of a smart polymer is the thermo-responsive polymer N-isopropylacrylamide (NIPAM) which is often used in tissue engineering applications. This material can be used to grow confluent cell sheets and then to detach the intact sheet along with the ECM that the cells have deposited.⁷³

Non-fouling materials

Another key challenge related to biomaterials is the foreign body response (FBR) seen *in vivo* with almost all synthetic biomaterials used clinically, be they polymers, ceramics, or hydrogels. Approaches to reduce the FBR to biomaterials *in vivo* may use physical properties, such as by creating spatial

Fig. 16.8 Effect of controlled release of a growth factor on tissue development *in vivo*. Cross-linked gelatin microspheres suspended in collagen were used to deliver fibroblast growth factor-2 (FGF-2) in a tubular mouse tissue-engineering chamber enclosing superficial epigastric vessels in the groin of mice, with (+) or without (-) an autologous fat graft. (From Vashi AV, Abberton KM, Thomas GP, et al. *Adipose tissue engineering based on the controlled release of fibroblast growth factor-2 (FGF-2) in a collagen matrix*. Tissue Eng. 2006;12:3035–3043.)

Fig. 16.9 Potential reversible responses of “smart polymers” to environmental stimuli. (A) Gelation. (B) Surface adsorption. (C) Collapse onto surface. (D) Swelling or contraction of hydrogel. (From Hoffman AS. *Applications of “smart polymers” as biomaterials*. In: Ratner BD, Hoffman AS, Schoen FJ, et al (eds). *Biomaterials Science*. Amsterdam: Elsevier, 2004;107–115.)

features that lead to reduced fibrosis (e.g., porous polymers with pores of around 30 μm ⁷⁴ or small-diameter fibers⁷⁵). Surface chemical properties can also be used to reduce the FBR to biomaterials, such as via attachment of oriented biomolecules.⁷⁶

One of the more successful strategies is the use of chemical surface modifications to create the so-called non-fouling surfaces. An initial stage of FBR is the adsorption of a complex layer of biomolecules from body fluids that can be denatured and lead to an immune reaction. Non-fouling materials (or stealth materials) resist the adsorption of these proteins. Usually these surface modifications make the material hydrophilic yet electrically neutral and the mechanism of action is believed to be that the surfaces hold their waters of hydration instead of allowing them to be displaced by adsorbing biomacromolecules. A myriad of strategies have been employed in order to generate non-fouling outer layers on biomaterials (e.g., by layer-by-layer assembly of polyelectrolytes ending with a nonadhesive outer layer,⁷⁷ or attachment of PEG^{15,78}). However, many strategies that show promise *in vitro* suffer from enzymatic attack and changes to the biomaterial surface *in vivo* during the acute inflammatory stages of the wound-healing response, and so their *in vivo* performance may be disappointing. Creating new generations of non-fouling materials with improved *in vivo* performance is an active area of research and includes candidates such as zwitterionic polymers, mixed charged polymers, and polyoxazolines.⁷⁹

Biofunctionalized materials

Cells will often attach to biomaterials implanted into the body, and this attachment is mediated by a layer of adsorbed proteins that contain cell binding sites. The abovementioned non-fouling technologies result in interfaces that do not adsorb proteins so are also resistant to cellular attachment. Such interfaces represent a “blank slate” for tissue engineers. These surfaces can then be decorated with bioactive molecules, usually through covalent immobilization. These biofunctionalized materials are then able to specifically interact with receptors on the cell surface and drive cellular behavior with biological specificity. The most common biofunctionalization strategy is to generate materials that contain ligands that engage specific integrin receptors. Thus, only cells that express the appropriate integrin are able to adhere to the material. The interaction of cells with such a surface depending on whether the surface has binding sites of suitable orientation and conformation to enable attachment of the cells, and the density of such sites. This in turn can affect cell morphology and migration rates (Fig. 16.10). Mostly these ligands are adhesion sites found in the native ECM (e.g., the RGD tri-peptide found in fibronectin),⁸⁰ but researchers have also performed analyses to discover unique receptors present on their cell type of choice. For example, a phage display library was screened in order to identify ligands specific to an outgrowth of endothelial progenitor cells but not other commonly occurring cell types. These ligands were then used to functionalize a biomaterial resulting in an interface inhabited exclusively by the target cell of interest.⁸¹

In addition to adhesion ligands, other bioactive molecules have been incorporated into synthetic materials in order to tailor biological interactions. For instance, the ECM acts to locally sequester growth factors, and similarly synthetic ECMs with tethered growth factors have been generated. Additionally, biofunctionalization has been used to tailor biomaterial degradation. The abovementioned biodegradable materials usually undergo some form of degradation reaction, for example hydrolysis of a chemical bond. This does result in a material that degrades; however, the degradation occurs regardless of cellular/tissue infiltration. However, cells move through the native matrix through secretion of matrix metalloproteinases that locally degrade the matrix. Advanced hydrogels that are crosslinked with peptide sites that are degraded by such metalloproteinases have been developed so that the biomaterial degradation rate adapts to the tissue growth rate.⁴⁸

Tissue engineering constructs

The abovementioned biomaterials are generally fabricated into a tissue scaffold to support regeneration. Usually, this

involves embedding cells within a hydrogel or incorporating microporous structures to enable cellular infiltration and metabolite diffusion. The design of biomaterial constructs for tissue engineering is complex and varies significantly depending on the tissue target. Even for specific tissue types, various design criteria may be considered (Box 16.2) and the definition of ideal designs is not yet well established.

Biomaterial constructs for tissue engineering can be fabricated into structures such as porous scaffolds and hydrogels, meshes or microspheres using a variety of techniques, including polymer phase separation, particle or foam templating, cryogelation, electrospinning and rapid prototyping methods like 3D-printing (discussed further in the emerging technologies

BOX 16.2 Key design criteria for tissue engineering scaffolds

Biomaterial selection, including:

- chemical composition
- molecular weight
- polydispersity
- crystallinity
- presence of any impurities (e.g., catalyst residues)

Internal 3D porous architecture:

- pore sizes
- pore shapes
- pore interconnectivity
- volume fraction of pores
- wall thicknesses

Surface chemistry

Surface topology

Degradation profile and products

Mechanical properties (initially and during degradation):

- elasticity
- strength
- toughness

Effects on cellular processes

In vivo effects (e.g., immune responses, foreign body reactions)

Ability to be fabricated reproducibly and economically

Ability to be sterilized without unacceptable property changes

Intracellular contraction forces Substratum adhesive strength	Large	Intermediate	Small
Typical cell morphology			
Migration speed	Negligible	Significant	Negligible

section).^{51,82–86} The techniques for tissue-engineering scaffold fabrication have been widely reviewed.^{53,87–90} A limited but growing range of biodegradable scaffolds are available commercially for cell culture and very specific approved clinical applications, examples of which are discussed in the case studies section at the end of this chapter.

Scaffolds of various internal architectures can be produced (Fig. 16.11) with different mechanical and degradation properties. The porosity must be interconnected and of sufficient size for molecular transport, cell migration, and vascularization. The size required may be larger than the minimum size

required to fit cells or blood capillaries. Cao *et al.* found that pores of at least 300 μm were needed for tissue survival in PLGA scaffolds where a significant FBR occurred inside the scaffolds.⁹¹

Ideally the mechanical strength of tissue-engineering constructs is matched to that of the target tissue to favor the desired cellular behavior, as discussed above, and ensure the construct will not collapse under the forces applied *in vivo* but will also not cause stress shielding to the surrounding tissue, which can lead to changes such as bone resorption. The construct should maintain its strength during tissue development

Fig. 16.11 Scaffold morphologies produced by thermally induced phase separation (A–C). (D) Particulate leaching. (E) Electrospinning. (F) Rapid prototyping. (A–C, Reproduced from Cao Y, Croll T, Cooper-White JJ, et al. Production and surface modification of polylactide-based polymeric scaffolds for soft tissue engineering. Precision extruding deposition (PED) fabrication of polycaprolactone (PCL) scaffolds for bone tissue engineering. *Biofabrication*. 2009;1:1–10.)

until the newly formed tissue can withstand the mechanical forces at play.⁹² Scaffold mechanics can be varied by adjusting the scaffold material, fabrication process, porosity (pore size, volume and architecture), grain size (for ceramics) and using composites such as nanoparticles of hydroxyapatite in a polymer matrix, as well as nanoparticle surface patterning.^{93,94} The effect of porosity in ceramics is illustrated in Fig. 16.12. Ceramics are prone to brittle failure and purely ceramic scaffolds with the porosity desired for effective vascularization may not have sufficient strength and toughness for load-bearing bone tissue engineering, which limits their clinical application.⁹⁵

Fabrication processes can incorporate viable cells and/or bioactive molecules with biomaterials by suitably gentle processes and scaffold-free construct production methods are also being developed, such as by using magnetic fields to arrange cells.⁹⁶

Vascularization in tissue engineering

The remarkable advances in tissue engineering during recent years have highlighted the importance of vascularization as it has become clear that survival, growth and function of an engineered construct are highly dependent on an adequate and timely blood supply. Generally, cells do not survive beyond 150 μm from a capillary,^{6,97} although certain cells and tissues vary in their oxygen needs. As stated earlier, whilst the first attempts of tissue fabrication were focused mainly on tissues of either low oxygen requirements, such as cartilage and tendon, or very small thickness, such as skin, able to survive by diffusion, it is now widely accepted that the fabrication of thicker and more “oxygen-demanding” surrogates cannot be conceived without first addressing the issue of vascularization, currently one of the major hurdles in translating laboratory-based tissue engineering products into human practice.

Fig. 16.12 Ceramic scaffold mechanical properties as a function of porosity. (From Boccaccini AR. *Ceramics*. In: Hench JRJ (ed.) *Biomaterials, Artificial Organs and Tissue Engineering*. Cambridge: Woodhead; 2005.)

Vasculogenesis, angiogenesis and inosculation

Understanding how the human vasculature develops, expands and connects to a grafted tissue is fundamental to successfully building a capillary network *in vitro* that is able to link to host's capillaries *in vivo* and ultimately support the growth, expansion and function of a tissue-engineered construct. *Vasculogenesis* refers to the development of new blood vessels from progenitor stem cells.⁹⁸ In the embryo, mesoderm cells are stimulated by FGF-2 to form hemangioblasts, a common precursor for vessel and blood cell formation. After pooling together into blood islands, hemangioblasts located at the periphery differentiate first into angioblasts and then into endothelial cells, which start to coalesce resulting in a primary vascular plexus.⁹⁹ Though initially it was assumed that vasculogenesis was exclusive to the embryological period, we know now that it also takes place in adult life driven by bone marrow-derived endothelial progenitor cells.¹⁰⁰ *Angiogenesis* describes the sprouting of blood vessels from pre-existing ones. Briefly, in this process endothelial cells respond to an angiogenic signal and increase vascular permeability allowing the extravasation of plasma proteins that form a transient matrix. A tip cell then migrates out of the vessel into the previously deposited matrix and leads the sprouting followed by stalk cells, which form a lumen. Once neighboring sprouts fuse, the neovessel becomes perfused and is further stabilized by the recruitment of pericytes and basement membrane restitution.¹⁰¹ *Inosculation* describes the process by which capillaries from a grafted tissue connect to those of the wound bed where it is applied. The exact mechanism by which such connection occurs and whether it is dependent on the characteristics of the grafted tissue are not entirely clear.^{102,103} What is clear, though, is that because it takes several days to ensue, inosculation is one of the limiting factors affecting prompt perfusion of a tissue-engineered construct.^{104–107} Such a period of time is too long to expect anything but very thin tissues to survive the transplantation anoxia. Nevertheless, some studies have achieved faster inosculation by using either fibroblasts or FGF-2, giving some interesting insights on how to accelerate the process and eventually make it clinically feasible.^{108,109}

Elements and strategies of vascularization in tissue engineering

As stated before, engineering of any 3D tissue or organ is highly dependent on an adequate blood supply. This can be achieved by either an extrinsic or an intrinsic approach. The extrinsic approach implies the direct implantation of a seeded scaffold that is gradually invaded by the host's vasculature, meanwhile relying solely on diffusion for survival. Alternatively, through a process named pre-vascularization, a capillary bed can be fabricated *in vitro* and then implanted *in vivo* where it will become perfused by inosculation rather than by capillary invasion (Fig. 16.13). In the intrinsic approach the organism is used as a bioreactor so that capillary sprouting occurs either before or concomitantly with cell differentiation and tissue growth.¹¹⁰ But before going into the detail of each of these approaches, one must first be familiarized with the different basic elements common to both strategies, which, similar to tissue engineering itself, are: cells, scaffolds and growth factors.

Fig. 16.13 Schematic illustration of the vascularization of a grafted tissue by inosculation and capillary invasion (angiogenesis). When a vascular network is fabricated prior to implantation, inosculation between the scaffold's vessels and bed capillaries at the periphery of the construct provides blood supply to the entire block. Conversely, if the scaffold is implanted without a pre-formed vascular network, adequate blood supply is only provided once host capillaries have completely invaded the construct.

Elements

Cells

A number of different cell sources have been trialed with varying degrees of success. In general terms, the vast majority of experiments attempting to build a capillary network use two cell lines, namely endothelial cells and supportive cells (Table 16.2). The logic in this is to try to mimic to some extent the processes of vasculogenesis and angiogenesis in which the lumen is formed by the endothelial cells while the stabilization and maturation of the newly formed vessels is partly the result of the structural and paracrine action of the perivascular supportive cells.

As can be seen in Table 16.2, there are a number of possible combinations. Whatever mixture is chosen, most of the latest research points towards better results obtained with bi-culture or even tri-culture compared with seeding endothelial cells alone.^{104,108,111,112} Additionally, it is interesting to note the fact

that adipose-derived stem cells have been used both as supportive and endothelial cells,^{113–115} with one study actually suggesting that ASCs alone may suffice for the formation of vascular lumina upon implantation.¹¹³ Of note also is the role of fibroblasts. As mentioned earlier, experiments using high concentrations of these cells have reported accelerated inosculation as early as one day post-implantation.¹⁰⁸ A further cellular element that has been explored with success in pre-vascularization is the stromal vascular fraction (SVF) from lipoaspirates. The presence of endothelial progenitors within the SVF cell population, as well as its remarkable proangiogenic potential, was reported more than a decade ago.^{116,117} More recently, other studies have reported on the successful growth of a functional capillary bed using SVF only.^{103,118} The current knowledge on the different components of SVF, namely mesenchymal stem cells, endothelial cells, endothelial precursors, vascular smooth muscle cells, pericytes and angiogenic growth factors make this lipoaspirate-derived cocktail a very reasonable and attractive source of the cellular elements needed to build a capillary network.^{119,120}

Scaffolds

The characteristics of scaffolds for tissue engineering have been described above. For vascularization, several of these matrices have been tested, all having their inherent pros and cons. Natural scaffolds include collagen, fibrin, starch, Matrigel®, decellularized matrix and silk fibrin. Synthetic materials on the other hand comprise mainly polyethylene glycol, poly (lactic glycolic) acid and polyurethane.¹²¹ Furthermore, clinically approved dermal substitutes such as Integra® and Matriderm® have also been used for prevascularization purposes by seeding them with endothelial colony forming cells (ECFCs) in association with either human dermal fibroblasts (hDFs) or bone marrow-derived mesenchymal stem cells (BMSCs).¹²² Whatever scaffold is used, it is important to consider the close cell–cell and cell–matrix interactions as well as the mechanical features that eventually guide and stabilize the newly formed vessels.¹²³ Likewise, since vasculogenesis and angiogenesis are deeply influenced by the presence of an

adequate extracellular matrix (ECM), it is equally important that the turnover between scaffold degradation and new ECM deposition by the cells occurs at a rate that neither impedes the growth of the network by being too slow, nor renders the construct unstable by being too fast.¹²¹

Growth factors

A complete and detailed explanation of the growth factors and signaling pathways involved in the process of angiogenesis is beyond the scope of this chapter. Herein, a general overview of the main growth factors that participate in the formation and sprouting of new blood vessels is presented.

Vascular endothelial growth factor A (VEGF-A) is the most important growth factor involved in angiogenesis in both health and disease,¹²⁴ acting mainly by binding to VEGF receptor 1 (VEGFR-1) expressed in endothelial cells, hematopoietic stem cells and inflammatory cells, and VEGFR-2, which is expressed mainly in endothelial cells. Additionally, neuropilins 1 and 2 (NRP1 and NRP2) are VEGF-A co-receptors, which can act either promoting VEGFR-2 activity or independently.¹⁰¹ Interestingly, the effect of VEGF-A on the developing vasculature is dependent on its isoforms and the way it is delivered. Thus, while soluble isoforms promote vessel enlargement, matrix-bound isoforms stimulate branching.¹⁰¹ Likewise, paracrine VEGF-A released by tumor, myeloid or other stromal cells increases vessel branching and renders tumor vessels abnormal retarding its progression,¹²⁵ whereas autocrine VEGF-A, released by endothelial cells, maintains vascular homeostasis.¹²⁶ As important as it is in the organism, VEGF-A has also been suggested to play a critical role in the design of clinically relevant tissue regeneration graft substitutes through its angiogenic effects and ability to chemoattract mesenchymal stem cells.¹²⁷

The fibroblast growth factor (FGF) family comprises 18 members that regulate a number of biological and developmental processes.¹²⁸ FGF-2 (also known as basic fibroblast growth factor, bFGF) is the one mostly involved in angiogenesis and is produced by a number of differentiated cells such as keratinocytes, mast cells, fibroblasts, endothelial cells and smooth muscle cells,¹²⁹ as well as by adult mesenchymal stem cells derived from bone marrow, adipose, and dermal tissue.¹³⁰ FGF-2 has been shown to exert a number of important actions related to neovessel formation such as stimulating migration and proliferation of endothelial cells *in vivo* and encouraging mitogenesis of smooth muscle cells and fibroblasts, which induces the development of large collateral vessels with adventitia.^{131,132} FGF-2 has been used with success in the prevascularization of scaffolds, with one study showing faster inosculation of the scaffold *in vivo* when this factor was added.¹⁰⁹

Platelet-derived growth factor (PDGF) and in particular PDGF-B released by endothelial cells also participate in the angiogenesis process mainly by attracting pericytes that will subsequently provide stability and structural support to the newly formed vessel.^{133,134}

Other proangiogenic factors identified are placenta-derived growth factor (PlGF), hepatocyte growth factor (HGF) and insulin growth factor 1 (IGF). Whilst these factors may play important roles in developmental and adult angiogenesis, for prevascularization purposes, it is likely that their role can be replaced by some of the other agents listed earlier, given the redundancy of factors and their functions.

Strategies

Extrinsic vascularization model of tissue engineering

The model of extrinsic vascularization relies on diffusion immediately after implantation until vascularization invades the construct from the periphery through into its core, a process that can take several days or weeks to be fully established. This model was the traditional prototype for 3D tissue engineering from its inception; nevertheless, it has become somewhat obsolete due to the growing knowledge on the importance of an adequate and prompt blood supply. Nowadays, it is mostly conceded that reliance on a 3D prefabricated structure to survive implantation by the random invasion of capillaries from the implantation bed is unlikely to be a viable concept, especially for tissues sizeable enough to be clinically useful. It may, however, still have a role in the engineering of thin or avascular tissues such as skin or cartilage. A number of animal models exploiting the extrinsic principle have been described (Box 16.3).

Interestingly, some studies have suggested that vasculogenesis in the subcutaneous model requires a significantly higher number of cells and growth factors compared with the brain, a fact that highlights the importance of implanting the scaffold in a well-vascularized environment to optimize perfusion.¹¹² To try to speed up the process, a number of modifications have been trialed to facilitate rapid vascularization upon implantation, including angiogenic growth factors,^{127,135} endothelial cells and MSC co-culturing for their angiogenic and paracrine effects,^{136,137} patterning of synthetic or collagen matrices with artificial vascular channels,^{138–141} bioactive scaffolds containing growth factors for controlled release,^{142–145} or decellularized whole-organ tissues that retain a skeletonized vascular tree which may be seeded with endothelial cells *ex vivo* or spontaneously endothelialized *in vivo*.¹⁴⁶ Additionally, cells may be subjected to ischemic preconditioning prior to seeding *in vivo* to tolerate the new environment better.^{5,147,148} Alternatively, current research is focusing on prevascularization, in which a capillary bed is built *in vitro* prior to implantation using a combination of the elements described previously. Once implanted, the capillaries on the periphery of the construct must inosculate with the recipient's vasculature to deliver oxygen and nutrients to the entire block (see Fig. 16.13). This approach, although not immediate, is seemingly faster and more reliable than waiting for the host's capillaries to invade the whole tissue from the periphery to its core, but still does not solve the issue of transient ischemia, which is not tolerated by a number of tissues. Even though some studies have achieved a significantly faster inosculation between 1 to 4 days,^{108,109,149} further research is still needed to establish this model of extrinsic vascularization as a feasible strategy for the engineering of sizeable 3D tissues. Finally,

despite the remarkable advances in the area of prevascularization that make us believe that the creation of thick, clinically relevant organs or tissues is within reasonable reach, there is yet an important hurdle to overcome, namely the fact that the vast majority of experiments are performed in healthy animals under relatively controlled conditions in comparison to the clinical scenario. In the latter, patients with damaged and scarred tissues, medical comorbidities, tobacco use and other adverse conditions are the substrate into which these prevascularized scaffolds will be eventually applied and expected to survive.

Intrinsic vascularization models and *in vivo* bioreactors

Prefabrication of flaps, where a blood vessel pedicle is implanted into living tissues to vascularize a dedicated territory such as skin,^{150,151} or prelamination, where several tissues are grafted around the pedicle so that they can be subsequently transferred as a composite tissue graft,¹⁵² has given tissue engineers insights into the importance of blood supply and how such vascularization might be incorporated into tissue-engineered products grown in the body.¹⁵³ This process involves the establishment of an intrinsic vascularization that grows in tandem with the tissue-engineered product and nourishes it progressively. When a vascular pedicle or loop is tunneled into a tissue plane, the surgical trauma, inflammation, and hypoxia stimulate release of proangiogenic growth factors and promote angiogenic sprouting, which links to the pre-existing vasculature (Fig. 16.14). We have exploited this concept for tissue engineering in a rat model, where a vessel loop is directed into a protected space that cannot collapse, such as a chamber box (Figs. 16.15–16.18).¹⁵⁴ The vessel loop sprouts new capillaries due to continuing ischemia within the chamber and shear forces in the loop further promote angiogenesis. The “wound” cannot contract or shut down, prolonging the ischemic stimulus, and altered mechanical forces and fluid shifts influence cell migration and proliferation within the chamber. The inflammatory environment of the chamber attracts neighboring and distant cells to participate in this frustrated repair process in an attempt to close the dead space, which is progressively replaced with new vascularized predominantly fibroblastic tissue (see Fig. 16.18). As the tissue grows, the angiogenic front moves centripetally and corresponds to the retreating zone of ischemia.¹⁵⁵ Tissue growth is enhanced when a collagen matrix is included in the chamber and the angiogenic tissue will readily accept a skin graft, thereby creating a vascularized flap. The angiogenic stimulus continues for at least 20 weeks but is maximal between 7 and 10 days (Fig. 16.19).¹⁵⁶ Simcock *et al.*³⁸ injected human angioblasts intravenously into rats with an arteriovenous loop chamber and observed that they could home to the chamber site. This was enhanced by SDF-1 delivery directly into the chamber and implies that vasculogenesis plays a role in the vascularization process (Fig. 16.20). The contribution of vasculogenesis to skin graft and flap healing has been elegantly investigated by Capla *et al.*¹⁵⁷ If fibroblasts are added to the chamber at the time of creation of the loop they survive and can proliferate.¹⁵⁸ We have developed a similar model of tissue engineering in the mouse using a “flowthrough” epigastric artery and vein in the groin surrounded by a sealed silicone tube, which includes Matrigel® matrix, a mouse sarcoma extract composed largely of laminin, and FGF,¹⁵⁹ which has also been described

by Walton *et al.*¹⁶⁰ (Figs. 16.21 & 16.22). We have studied the mechanism of angiogenic invasion into Matrigel®, as has been done also by Tigges *et al.* in mice.¹⁶¹ This highlights the pre-eminent role of bone marrow-derived macrophages and pericytes. Macrophages burrow into the matrix, creating channels which are lined initially by pericytes. Only later do endothelial cells follow and line the hollow tubes. Vessel-like networks form initially without any endothelial cell contribution but these cannot form without macrophages. This elegant exposé of the process of vascularization was specific to Matrigel® and may not necessarily reflect the vascularization process of wounds comprising other matrices. This intrinsic system of vascularization can support seeded cells and the histological pattern of their survival clearly demonstrates the intimate role of the neovasculature in nourishing the cells. Fibroblasts¹⁵⁸ as well as specialized cells including neonatal cardiomyocytes¹⁶² (Fig. 16.23), islet cells,¹⁶³ and myoblasts⁵ survived in the chambers but quantification of survival is difficult and almost certainly many cells apoptose. Delayed seeding of cells into a prevascularized chamber enhances cell survival in the rat⁵ and mouse chambers.¹⁶³ When ASCs were implanted into the mouse chamber model in Matrigel® and traced by sex mismatching or human to animal stains, new fat tissue formed but the stem cells were found to contribute only to new blood vessel formation. New fat was of host origin, indicating that the stem cells did not differentiate into fat but were inductive for endogenous fat formation. It is well recognized that MSCs have paracrine effects, including angiogenesis, cell recruitment, homing, anti-inflammatory, and antiapoptotic effects.¹⁶⁴ We have compared survival of liver precursor cells cultured on 2D plastic delivered as cell suspensions with 3D gel-cultured spheroids.¹⁶⁵ In the spheroid form greater numbers of cells implant and survive in the chamber, suggesting that survival is related to other factors such as cell–cell microenvironment apart from pure vascularization. When solid tissue pieces such as muscle were implanted into the chamber they did not survive but regularly the dead tissue induced endogenous fat replacement.¹⁶⁶

Khouri *et al.*¹⁶⁷ designed a tissue-engineering chamber (BRAVA®) to induce fat growth for breast tissue replacement. It consists of a suction device applied to the external surface of the breast which, when worn regularly for prolonged periods, pulls the tissue away from the chest wall, creating tissue injury, inflammation, and a potential space. These are the key elements of our tissue engineering chamber where inflammatory cytokines stimulate angiogenesis and attract stem cells while the vacuum creates the space. Biomechanical forces including fluid shifts also influence cell behavior. Subsequently, Khouri included massive volumes of fat injection which are seen to survive most probably thanks to the well-vascularized environment generated by the previously applied suction.^{168,169} This modification is akin to our model of seeding cells into a preconditioned prevascularized chamber. In another original concept of intrinsic vascularization for tissue engineering using “autologous microcirculatory beds”, Chang *et al.*¹⁷⁰ devised an *ex vivo* perfusion chamber where an explanted flap of tissue, which is in essence a preformed vascular bed, can be continuously perfused with oxygen-carrying nutrient fluids for periods of up to 24 hours through its vascular pedicle. During this time, the flap was infused with cells intravascularly, including stem cells, which egressed from the microcirculation into the tissues to form cell

clusters. The flap was then reimplanted by microvascular anastomosis into the animal. Similarly, Sekine *et al.*¹⁷¹ have also harvested a capillary bed using a piece of rat femoral muscle tissue attached to the femoral artery and vein. After connecting it to a bioreactor and perfusing it, the authors placed cell sheets containing cardiac and endothelial cells and demonstrated functional connections between the sheet and the bed. These authors also found that the co-culture of endothelial and cardiac cells as well as the addition of FGF-2 led to a more robust vascularization of the tissue in the bioreactor. Finally, they were able to transplant the whole construct back into the rat as a microsurgical free flap using the carotid artery

and jugular vein as recipient vessels. This model points to a new direction in organ regeneration or cell transfection to deliver deficient proteins. Furthermore, it is indeed attractive in the sense that it circumvents the need to “artificially” create a vascular network and ensures immediate vascularization after pedicle anastomosis without having to rely on invasion or inosculation. Moreover, at a first glance this method seems applicable to soft tissue reconstruction by harvesting a pedicle with a small amount of tissue which is expanded *in vitro* and transplanted back into the patient; however, it unfortunately still involves the sacrifice of a vascular pedicle with its inherent donor site morbidity.

In a different model of intrinsic 3D tissue engineering, a vascularized flap of fat tissue, when implanted into an empty chamber space, will expand and attempt to fill the space. We initially observed in our mouse Matrigel® model that if a fat pad was used to plug one end of the chamber tube and wax the other, fat gradually replaced the Matrigel® by direct extension from the pad.¹⁵⁹ When we placed an isolated fat pad on a vascular pedicle into the chamber in a rat even without matrix, the fat tissue expanded. When perforations were included in the chamber shell the space completely filled with tissue, approximately 40% of which was new fat.¹⁷² This result was repeated in a pig model which grew over 50 mL of new fat (Fig. 16.24).¹⁷³ Although surgical trauma, ischemia, and inflammation play a role through biochemical signaling in this new tissue growth, it is likely that the tissue flap finding itself in an empty space reacts to the changed biomechanical

environment through focal adhesion transmembrane pathways as discussed earlier,⁴¹ stimulating cell migration and growth. However, quantification of this effect is difficult *in vivo* and the precise process remains unclear.

Encouraged by the promising findings in animals, we questioned whether the tissue-engineering chamber might have a similar effect in the clinical setting and thus we scaled up our research into a human trial.¹⁷⁴ Five patients were recruited, all candidates for breast reconstruction who wished to avoid breast implants if possible and were unsuitable for autologous reconstruction. A pedicled fat flap based on the thoracodorsal system ranging from approximately 5 to 50 mL was harvested, transposed onto the chest wall and placed inside a perforated, acrylic, custom-made chamber ranging from 180 to 360 mL. Magnetic resonance imaging was performed every three months and the chambers removed six months after implantation. One patient was withdrawn from the trial at 7 weeks due to painful rubbing of the chamber's rim on her ribs. In another patient there was significant expansion of the flap by 6 months on MRI and it was mutually agreed to leave the chamber *in situ* for twelve months total. At exploration the whole chamber space had filled with fibrofatty tissue surrounded by a fibrous capsule representing an

Fig. 16.24 (A) Chambers in pig model, 80 mL volume. (B) 5 mL volume fat flap on epigastric pedicle inserted into the chamber. (C) Buried for 6 weeks. (D) Removal at 6 weeks, filling the chamber. (E) Approximately 50% volume is new adipose tissue.

expansion of the flap from approximately 30 mL to 210 mL (Fig. 16.25A,B). Conversely, the flaps in the remaining three patients failed to expand and instead were encased in a thick fibrous capsule. Although the trial was unsuccessful, the unquestionable finding of stable tissue growth to the chamber's capacity in one of the patients, which was stable at 6

months after chamber removal (Fig. 16.25C), provides a proof-of-concept that clinically relevant volumes of autologous tissue can be generated using the tissue-engineering chamber in humans. The difference in the consistency of results within this trial and in comparison to those obtained in animals warrants further investigation.

Fig. 16.25 (A) Intraoperative view upon chamber removal. The space is completely filled with fibro-fatty tissue surrounded by a fibrous capsule. Original flap volume was 30 mL and chamber space 210 mL. (B) Detail of tissue generated inside the chamber showing adipose tissue under fibrous capsule. (C) Patient at six months after chamber removal. Newly formed tissue remained stable and softened to a “fat-like” consistency. Emerging technologies

A range of engineering and technology developments that may significantly impact tissue engineering have emerged over recent years.

3D printing

The most striking development is additive manufacturing via 3D printing, sometimes termed bioprinting or bioplotting

when biological components are included. Whilst this technology has been known for processing plastics for over 30 years, major improvements in the last decade have led to simultaneous reductions in the costs involved and dramatic increases in flexibility. Various types of printing equipment can now be used to produce three-dimensional objects from computer-aided designs (CAD) simply and affordably, as illustrated in Fig. 16.26. At its simplest, a 3D printer resembles a hot-glue gun or syringe delivery system that lays down droplets or fibers of a chosen material in 3D patterns built up

Fig. 16.26 Methods of producing three-dimensional (3D) biomaterial constructs via solid freeform fabrication. (A) Stereolithography. (B) Selective laser sintering. (C) 3D printing. (D) Wax printing. F, From Hollister SJ. *Porous scaffold design for tissue engineering*. Nat Mater. 2005;4:518.)

layer by layer as the printer nozzle and/or printing stage move according to the CAD requirements. A wide variety of materials can be processed using different kinds of 3D printers, including polymers, hydrogels, metals, ceramics and even living cells. Many detailed reviews have been published on aspects of this technology and its potential in tissue engineering in recent years.^{88,175}

Many 3D printers and other forms of rapid-prototyping equipment are limited to a certain category of raw materials, e.g., photo-polymerizable or melt-processable polymers with specific physical properties. However, this limitation is also being overcome with printers such as the 3D-Bioplotter (EnvisionTEC GmbH), which are able to print in numerous user-developed materials including melt-processed polymers, hydrogels and viable cells.^{175,176} It is also possible in many devices to print multicomponent mixtures in defined patterns to create more complex objects. Challenges remaining to be resolved with this rapidly evolving technology include the potential of damage to cells and biomolecules during printing due to shear forces in the nozzles, particularly when high spatial resolution is desired. Different printing methods have limitations in material choices and printed construct properties such as pore and fiber size ranges, construct surface properties (e.g., roughness) that can affect cell-material interactions, as well as accuracy, processing cost and speed. Appropriate quality control, predictability of properties such as construct mechanical strength and defect frequencies, the ability to print in a diverse range of medical grade materials, as well as regulatory and industry guidance are areas for further improvement before this technology can be widely adopted in tissue engineering.¹⁷⁷

3D printed polymer scaffolds have been used clinically in a range of applications, mainly for hard tissue repair, typically by creating a customized implant using medical imaging data for a particular tissue defect in a patient. Notable examples include scaffolds for craniofacial bone repair and some recent reports on airway splints for tracheobronchomalacia.^{95,177} Such biodegradable scaffolds or implants are sometimes termed “4D” as they change with time, ideally resorbing as the patient’s tissues develop.

Another area of rapidly increasing activity is production of tissue- or organ-on-a-chip modules often created using microfluidic devices and 3D printing. Such constructs rely on tissue engineering principles and provide opportunities to study tissue development, diseases and screen drugs in more realistic *in vitro* environments.^{178,179}

While biofabrication via 3D printing facilitates the manufacture of custom-designed tissue engineering constructs with excellent spatial control of the initial distribution cells and biomaterials, the major challenge of achieving timely vascularization in 3D tissue engineering constructs discussed above for constructs made in other ways, still applies for 3D-printed constructs. This is often neglected in reports about the potential of this technique, especially in the media where hype sometimes overtakes reality. Research to address this problem has included inclusion of interconnected channels in 3D-printed constructs to allow perfusion *in vitro* and in a recent development, Kolesky *et al.* used a custom-made bioprinter to fabricate heterogeneous constructs that included multiple cell types and vascular channels lined with endothelial cells.¹⁸⁰

In vitro bioreactors

Cell culture in 3D constructs presents challenges in delivery and removal of nutrients and waste products in the absence of a blood supply.¹⁸¹ The delivery of oxygen is challenging due to its relatively low solubility in cell culture media and the time required for diffusion to occur into human-scale 3D constructs. Delivery of macromolecules such as growth factors also presents challenges due to their large size and thus relatively slow diffusion. In addition, mechanical forces, hydrodynamic conditions and electrical stimulation can significantly affect cellular processes and tissue development. Therefore, advanced bioreactors may be helpful to control the microenvironment of cells *in vitro* to encourage the desired cellular processes and tissue development whilst also optimizing the mass transport of oxygen, nutrients and waste products to allow 3D tissue constructs to be developed.¹⁸²

Computational modeling

Mathematical modeling can assist in design of tissue-engineering constructs and processes, providing insights into factors governing tissue growth. For example, different cell-seeding patterns and timing can be investigated using a mathematical model of a tissue-engineering scaffold during vascularization *in vivo* to provide insights into oxygen concentration distributions and cell migration rates. Such models are necessarily simplifications of the complexity of the biological processes at play but may aid experimental design and interpretation and so help reduce trial-and-error experimentation and animal use.^{183,184}

Testing and characterization of tissue engineering approaches

Characterization of new or modified biomaterials, cells, and methods for tissue engineering is critical to their potential pathway to clinical trials and ultimately to clinical and commercial success. Systematic testing is not only a requirement of regulatory and ethical approval during the development process, but also crucial to developing understanding and thus being able to improve tissue-engineering methods further. Testing should aim to allow prediction of the long-term safety and efficacy of the tissue-engineering approach under consideration. Ideally, *in vitro* testing would be used to screen tissue-engineering constructs and methods in order to minimize animal testing for ethical reasons. However, it remains a significant challenge to predict *in vivo* responses from *in vitro* tests and so significant animal testing is normally required before clinical trials.

Standardized testing methods are highly desirable so that objective comparisons can be made between different approaches and construct components across different laboratories. Testing should be undertaken under conditions simulating the targeted tissue-engineering application, rather than relying on test results for the same material in different applications where phenomena may differ significantly.¹⁸⁵ Physicochemical characterization of biomaterials and constructs made from biomaterials should be undertaken to ensure the targeted composition, absence of significant residues or impurities, and desired morphology are achieved.

Materials which are nominally the same may perform differently in tissue-engineering applications due to differences such as the presence of impurities, differences in molecular weight or polydispersity in polymers, or variations in surface properties.

Risks, ethics and regulation

Risk management is a critical consideration in clinical and commercial tissue-engineering efforts. A number of potential products developed early this century suffered from problems with regulatory trials and product launches, along with challenging investment conditions internationally.¹⁸⁶ Tissue-engineering approaches have significant potential benefits to patients and the health system but also involve risks, which may include human error (e.g., mix-ups of autologous cells), biomaterial performance variations from predictions (e.g., changes in degradation rates *in vivo*), quality control problems (e.g., microbiological contamination), and variations in patient-specific responses. Most of these can be minimized by rigorous management and scientific processes (e.g. through GMP process requirements, process automation and quality control), whilst patient-specific responses will only be fully assessed once sufficient clinical trial data have been collected. Many of the commercial successes in the field of tissue engineering to date have avoided the risks involved in delivering biological materials, rather using acellular products.¹⁸⁶

The ethical considerations related to tissue engineering have been reviewed^{187,188} and many of these are common with other fields of medicine and biomaterials. The sources of biological material to be used, particularly the potential use of ES cells, are, unsurprisingly, prime considerations. The extent of animal testing is a further issue of concern, which may be partly addressed by effective *in vitro* testing and well-designed experimental approaches, as discussed above. Animal trials should be designed to simulate the final clinical application as closely as possible to avoid incremental approaches to the final design with numerous animal trials at every stage.

The regulatory approvals required for tissue-engineered products depend on the jurisdiction involved and have evolved significantly over the last decade around the world. In the case of the US Food and Drug Administration (FDA), products may be characterized as tissues, biological products, medical devices, or combination products and numerous standards and guides have been developed for particular categories of products.^{189,190} The ISO10993 series of standards addresses "Biological Evaluation of Medical Devices" and numerous ASTM guides provide details on testing and characterization requirements for different types of tissue engineering products.

Case studies and status of tissue engineering for specific tissues

Skin tissue engineering

Biological wound dressings have been long-established from cultured sheets of keratinocytes,¹⁹¹ and together with skin banks this has saved the lives of many burns patients.

However, graft durability and functionality is often poor, with wound contraction, scar formation, and impaired sensation being frequent complications in addition to graft failure. To improve this, skin tissue engineering has focused on generating a dermal component in addition to the epidermal layer. Such tissue-engineered skin substitutes would function beyond simple wound coverage and barrier protection. They could be applied in the treatment of chronic wounds with impaired wound healing such as diabetic ulcers, in skin disease models for example with vitiligo and psoriasis, and for drug and cosmetic testing. Additionally, oral mucosa tissue engineering draws many similarities with skin,¹⁹² and this will no doubt be useful in craniofacial reconstructions.

The principles of skin tissue engineering follow the same concept as other tissues and involve cells, scaffold, and vascularization. Cell sources include fibroblasts to promote collagen and other ECM structural integrity but also to address the fundamental problem of biofilm that protects bacteria from attack by neutrophils and renders local fibroblasts senescent. Live fibroblasts can be incorporated into the implant to attract and activate neutrophils through the secretion of proinflammatory cytokines and growth factors.^{193,194} Other cell types include epidermal-derived stem cells,¹⁹⁵ and MSCs especially for wound healing,¹⁹⁶ and melanocytes.¹⁹⁷ Bulge cells from hair follicles and co-cultures, especially with neonatal dermal fibroblasts, offer some hope of regeneration of functional skin elements, including hair follicle and sebaceous glands.¹⁹⁸ Cutaneous nerve regeneration may be enhanced through the addition of Schwann cells, or epidermal-derived stem cells and other MSCs which are capable of differentiation into both neurons and Schwann cells.¹⁹⁹

Scaffolds are a key aspect of engineered skin. Substitutes initially served as passive matrices for ingrowth from the wound bed full of blood vessels and dermal elements, but more recently complex structures have been developed comprising of biomimetic proteins and material, 3D culture techniques, and altered surface chemistry and topography to influence cell adhesion, growth and differentiation, durotaxis, spatial cueing, and mechanoregulation.^{200,201} They can also facilitate nerve regeneration,¹⁹⁹ and may include antibacterial agents such as PLGA films and polylactic acid nanofibers loaded with silver ions or nanoparticles.^{202–204}

Current products suffer from poor integration to the wound bed as a result of inadequate vascularization and this impacts on the survival of implanted cells. Recent efforts to address this include the use of angiogenic biomaterials and prevascularization of constructs (covered in earlier sections), as well as the use of stem cells such as adipose-derived stem cells which abundantly secrete angiogenic growth factors and can also contribute directly to regeneration by differentiating into fibroblasts, epithelial, and endothelial cells.²⁰⁵

Adipose tissue engineering

Adipose tissue engineering holds great interests to plastic surgeons for reconstruction of soft tissue deformities such as Poland syndrome, Romberg syndromes, aging, breast post-mastectomy and traumatic deformities, burns, and postirradiation defects.

Adipocytes are fragile, prone to ischemic death,²⁰⁶ very difficult to grow in cell culture, and do not proliferate *in vivo*. Consequently, precursor populations derived from bone

marrow or fat SVF and sorted by adherent cell culture or fluorescence-activated cell sorting (FACS) are the preferred cell source for the traditional loaded-scaffold paradigm of tissue engineering. However, this direction has been singularly unsuccessful for fat, no matter what scaffold is chosen, and most clinically focused research is returning to modifications of fat injection, possibly with matrix material as a more likely route to clinic.

Attempts to understand the fate of fat-grafting dates back almost a century when Marchand²⁰⁷ grafted fat onto the brain of animals. Upon exploration, he identified two cell types: (1) fat, which he interpreted as having survived a graft; and (2) histiocytes, which had come from the hosts and appeared to be turning into fat, which he labeled as replacement. Since then, a long debate ensued as to whether cells in grafted fat survive or signal endogenous fat production. When we inserted human fat grafts into our mouse chamber tissue-engineering model containing Matrigel® and FGF-2, new fat formed but it was of mouse origin (Fig. 16.27). Similarly, when

Fig. 16.27 (A) Spontaneous endogenous fat formation in Matrigel® in a mouse model of tissue engineering after insertion of a small nonvascularized fat allograft. (B) Normal fat tissue grown in the chamber. Note the extensive vascularization sprouting from the vascular pedicle. (Courtesy of F. Stillaert, O'Brien Institute.)

FACS-sorted or SVF-derived human ASCs or bone marrow stem cells were implanted, endogenous fat formed.²⁰⁸ If the fat graft or stem cells are substituted by an inflammagen such as yeast particle zymosan, fat also forms in Matrigel®.²⁰⁹ Taken together with the early appearance of macrophages in the chamber and their critical role in angiogenesis and adipogenesis as shown by macrophage ablation studies,²¹⁰ it suggests that the signaling mechanism by which fat grafts stimulate fat growth is an inflammatory one. This is consistent with the emerging notion that MSCs largely function through their paracrine effects especially to promote angiogenesis and cell signaling. The cytokine profile of the mouse chamber contents clearly shows inflammatory angiogenesis predominating for the first 7 days, at which time it changes to adipogenesis with the appearance of peroxisome proliferation-activated receptor- γ and other markers.²¹¹ Whether this event sequence is peculiar to Matrigel® matrix is not yet clear. Nevertheless, increasing evidence suggests that initial cell death within fat grafts is followed by neoadipogenesis, which is mediated by stem or progenitor cells within the grafted material with the recruitment of host cells at the implantation site.^{212,213} This is supported by recent clinical studies reporting the enhanced survival of fat grafts enriched with SVF/ASCs when compared to fat grafts alone.^{214,215} However, whether the fat graft itself survives at least in part remains unanswered, with a wide variability of results in the literature.²¹⁶ Furthermore, questions remain as to whether the stem cells themselves survive and contribute directly to new fat, or if they represent a concentrated dose of inflammatory paracrine factors which induce endogenous fat production.

Matrix plays a key role in adipogenesis, as does angiogenesis. Multiple synthetic and natural scaffolds have been trialed *in vitro* and *in vivo* with and without FGF and/or seeded cells. Matrigel® is both angiogenic and adipogenic,²¹⁷ and several Matrigel® substitutes are under study, including derivatives of muscle (myogel)⁵⁵ and adipose-derived matrix (ADM).²¹⁸ The ultimate clinical product would be an adipogenic injectable matrix gel with or without processed lipoaspirates. ADM has so far shown promise in stimulating the adipogenic differentiation of ASCs both *in vitro* and *in vivo*,²¹⁸ and can be used as an off-the-shelf product to regenerate subcutaneous fat in soft tissue defects created in the rat back.²¹⁹

Another important area is the role of mechanical forces that influence cell behavior, including differentiation. We believe this is critical to the growth seen in the chamber space, particularly in those models where there was no matrix or seeded cells such as the adipose tissue growth seen in the pig model (see Fig. 16.24) and clinical study (see Fig. 16.25), corroborated more recently by others using a rabbit model.²²⁰

Muscle tissue engineering

Tissue engineering of skeletal muscle has potential *in vivo* applications for the treatment of muscular dystrophy, muscle loss from injury and post-tumor resection, chronic denervation, and targeted delivery of proteins and drugs by gene transfection of muscle cells. *Ex vivo* applications could include models for the study of exercise physiology or muscle diseases or drug screening. It could also in theory find a commercial use for tissue-engineered meat production from animal stem cell sources.²²¹

Muscle is unique functionally with its densely packed parallel-aligned multinucleated muscle fibers which contract axially through calcium-sensitive actin and myosin filaments. This in turn involves neural connections functionally linked through acetylcholine release and its receptors. Addressing this specialized architecture with the incorporation of vascular and somato-sensory elements to create fully innervated, vascularized skeletal tissue that can be transplanted and function *in vivo* remains a major challenge.

Cells used for muscle tissue engineering include myoblasts, the progenitor cell to mature myocytes which can be isolated from skeletal muscle and expanded *in vitro*. However, differentiation in 2D culture after extended passaging is difficult, and requires ECM coating or 3D culture to facilitate myoblast alignment and differentiation.^{222,223} Another cell source includes the more immature satellite cells, which are resident stem cells in skeletal muscle residing below the basal lamina of myofibers. They represent 2–7% of the cell population in adult muscle and are capable of self-assembly into new myotubes following injury and stimulation.²²⁴ However, expansion of these cells after isolation is problematic, with reduced proliferation and regenerative capacity with prolonged culture.²²⁵ Satellite cells can be replenished by pericytes, which are found in the walls of small blood vessels.²²⁶ Pericytes isolated from a wide variety of tissue including skeletal muscle are also capable of myogenesis both *in vitro* and *in vivo*, regardless of tissue origin.²²⁷ They are closely related to mesoangioblasts, which are perivascular cells found in larger vessels and are also capable of contributing to muscle regeneration.²²⁸ Both pericytes and mesoangioblasts are phenotypically similar to MSCs, which are also attractive candidates. MSCs can be derived from a wide variety of tissues, as discussed above, home into sites of injury, secrete useful paracrine factors, and directly contribute to new muscle.²²⁸ More recently studies have also focused on the generation of myoblasts, myogenic MSCs, and mesoangioblasts from pluripotent stem cells such as iPS or ES cells.^{229–232} This opens a gateway for the use of autologous cells for tissue engineering, as well as the transplantation of genetically corrected cells for conditions such as muscular dystrophy.²²⁹

Strategies to improve the myogenic differentiation of cells include the use of 3D perfusion bioreactor systems²³³ and co-culture of myoblasts with various other cells such as SVF (containing ASCs)²³³ and fibroblasts.²³⁴ Co-culture with neural tissue in a 3D matrix can also enhance *in vitro* muscle function,²³⁵ as well as generate neuromuscular junctions with functioning acetylcholine receptors.²³⁶ Electrical stimulation of myoblasts in 3D collagen culture mimics nerve stimulation and promotes differentiation to myotubes and ECM deposition.²³⁷ Mechanical stretch or force organizes myoblasts into functionally aligned myotubes and favorably influences fiber diameter and cell number^{238,239} by myofilament gene regulation and protein expression.^{240,241} *In vitro* preconditioning of myoblasts by cyclic strain in a bioreactor improved the contractility of engineered tissue.²⁴² Other specialized culture systems include the co-culture of myoblasts with fibroblasts on Seran wrap or laminin-coated plates stretched out between pins. This led myoblasts to orientate themselves axially and separate from the wrap upon differentiation to assemble into a cylindrical core of contractile muscle using the pins as tendon-like anchors, which were termed as myoids.^{243–245} More recently, sophisticated approaches to cell alignment

include the manipulation of the cell culture surface topography using nano/micro-patterning techniques, ECM printing, as well as the application of mechanical strain and electromagnetic fields in order to generate myotubes and skeletal muscle sheets.²⁴⁶

ECM compositions play a key role in the alignment and differentiation of myoblasts. Hydrogels facilitate self-assembly of suspended cells into transplantable constructs, and collagen,²⁴⁷ fibrin,²⁴⁸ alginate,²⁴⁹ hyaluronic acid,²⁵⁰ PEG,²⁵¹ and extracellular matrix derivatives such as Matrigel^{®252} and myogel²⁵³ have been used. Various synthetic matrices, including PLGA mesh,²⁵⁴ PCL,²⁵⁵ chitosan,⁹³ glass fibers,²⁵⁶ electrospun nanofibers,^{257,258} and wavy silicone surfaces²⁵⁹ influence regulation of cell alignment differentiation and proliferation but the elasticity, toxicity, and biodegradability are critical to *in vivo* application. Decellularized biological scaffolds may be more physiologically attuned with this regard, as they contain relevant ECM components in their relative compositions, are non-immunogenic, have a preformed shape, and likely retain biologically active cytokines and growth factors and functional cues. Decellularized scaffolds from porcine urinary bladder (MatriStem[™]) have been used to stimulate local muscle regeneration in patients with volumetric muscle loss following severe leg injury.²⁶⁰ By placing these scaffolds within the injured muscle close to viable tissue followed by intensive physical therapy, biopsy at 6–8 months showed new muscle tissue with resorption of the scaffold, correlated with CT/MRI imaging. Improved functional outcomes were reported in 3 out of 5 patients despite an original muscle loss ranging from 58–90%. It is expected this could be further optimized through the addition of cells to the scaffold, such as in a study where decellularized skeletal muscle was reseeded with myoblasts, fibroblasts, perivascular stem cells, and endothelial cells and used to reconstruct a rat abdominal wall defect.²⁶¹ This approach has also been taken to reconstruct a bioartificial limb from decellularized rat and primate forearms.²⁶² Scaffolding from the soft tissue including muscle was recellularized in a bioreactor with endothelial cells, myoblasts, and fibroblasts followed by electrical stimulation and coverage of the forearm with a skin graft (Fig. 16.28). Despite no integration of neural tissue, the rat paw was seen to clench and unclench in response to electrical stimuli with approximately 80% the strength of a newborn rat. Functional anastomosis of blood vessels could be achieved upon transplantation of these forearms with preserved response to electrical stimuli. Although this remarkable proof-of-concept study still requires many steps to become clinically relevant, it provides encouragement in the field of decellularized scaffolds.

Vascularization remains a large hurdle in the upscaling of engineered tissue *in vitro*, and the survival of transplanted tissue. In recognition of this, *in vitro* approaches may combine myogenic cells with endothelial cells within 3D scaffolds,^{263,264} or combine the delivery of growth factors such as VEGF or insulin-like growth factor 1 together with cells in a scaffold.^{247,265} Scaffolds themselves can be tailored to have sustained release of these growth factors to mitigate their short half-life, and encourage blood vessel ingrowth from the host into the engineered tissue upon transplantation.²⁶⁶ Applying intrinsic vascularization is another option, and we have used both the mouse flow-through pedicle model and rat arteriovenous loop model to demonstrate the survival of implanted myoblasts.^{252,267} Cell survival can be enhanced through the use

Fig. 16.28 Recellularization of decellularized rat arm scaffolds. **(A)** Progressive decellularization of whole rat arms. **(B)** Recellularization of arm scaffold. (A, Reprinted from Jank BJ, Xiong L, Moser PT, et al. *Engineered composite tissue as a bioartificial limb graft*. *Biomaterials*. 2015;61:246–56, with permission from Elsevier. B, Reproduced with permission from Dr. Harald C. Ott and Dr. Bernhard J. Jank, Massachusetts General Hospital and Harvard Medical School.)

of techniques such as *in vitro* preconditioning to stimulate pro-survival signaling pathways (Akt and ERK1/2), or *in vivo* prevascularization with delayed seeding to prepare a dense capillary bed prior to cell delivery. However, to generate larger volumes of vascularized three-dimensional skeletal muscle it is likely that a combination of vascularization strategies would be required during both the *in vitro* and *in vivo* phase, with amalgamation of advances in cell co-culture, growth factor delivery, scaffold tailoring and intrinsic vascularization. This will need to be accompanied by appropriate electrical stimulation and neuronal integration to maintain the growing muscle tissue.

Tissue engineering of nerves

Nerves in different locations have distinct microenvironments and thus the optimal tissue-engineering strategies for each will differ. Tissue-engineering strategies may be used for guided nerve regeneration using, for example, degradable biomaterial tubes or scaffolds. There are now a range of FDA/Conformit Europe approved neural scaffolds available which largely consist of collagen I, but include PVA, PCL and decellularized matrix derivatives.²⁶⁸ Hollow tubes can function effectively as nerve guides for gaps of up to 10 mm in the peripheral nervous system under a range of clinical situations. For example, tubular collagen nerve guides (NeuraGen®, Integra LifeSciences) are being used clinically to treat peripheral nerve injuries.²⁶⁹ The critical gap length that may be successfully treated using nerve guides can be longer than 10 mm in primates and can be further increased by addition of cells and cell supports such as biomaterial fibers or hydrogels.²⁷⁰ It has been shown that use of oriented hydrogel matrices (e.g., fibrin or collagen) within nerve guides results in a larger critical gap length than use of the same matrices without alignment. Electrospun fibers can provide mechanical support to guide nerve regeneration, depending on their diameter, alignment, and spacing, and nanofibers may also be developed within a hydrogel.²⁷¹ Including conductive materials such as gold nanoparticles or carbon nanotubes can facilitate the use of electrical stimulation, which can increase neurite outgrowth and maturation.^{272,273} Schwann cell grafts including those generated from iPSCs,^{274,275} and the addition of controlled-release vehicles containing drugs or neurotrophic

factors can also increase the success of tissue-engineering strategies for nerves.^{268,276} Three-dimensional printing could be used in the fabrication of these nerve guidance conduits, and there is potential to integrate this technology with bionic limbs by connecting bioengineered scaffolds as nerve guides to electrodes in the prosthetic limb.

The environment and cellular responses to injury in the central nervous system tend to inhibit regeneration. Stem cell therapies for spinal cord injury including several human trials have shown some regenerative responses, but the mechanisms of how they may repair the spinal cord are not well understood.²⁷⁷ Direct contribution to new tissue, release of trophic factors, and modulation of inflammatory cytokines particularly in the early stages of injury have been postulated. Tissue engineering could be applied in this area to enhance the delivery of regenerative cells, scaffolds, and neurotrophic factors to promote axonal regrowth following injury. Scaffolds or hydrogels can aid cell adhesion, retention and differentiation, or be used to deliver growth factors and drug molecules, and oriented pores and channels can guide axonal growth.²⁷⁸ Interestingly, the use of an acellular scaffold may forestall immediate scarring of the spinal cord following injury, providing a more permissive regenerative environment.²⁷⁹

Tissue engineering of blood vessels

A number of strategies to tissue engineer blood vessels *in vitro* or *in vivo* as an alternative to autografts, allografts, or nondegradable polymer prostheses have been developed and tested in animal models and in the clinic with promising results.²⁸⁰ The engineering of capillary networks in scaffolds has been covered earlier in the chapter, but advances have also been made in the development of larger macrovessels. Collagen-based scaffolds containing a polyester mesh are available commercially (Omniflow II from Bio Nova International) and are used clinically as a biosynthetic vascular graft for hemodialysis access.²⁸¹ Decellularized veins have been used as allografts, although a high rate of aneurysmal and thrombotic complications have been noted.²⁸² Grafts have also been made by culturing allogeneic smooth muscle cells on PGA scaffolds to encourage ECM deposition and remodeling of the synthetic material, followed by detergent-based removal of these cells to retain only the ECM skeleton.²⁸³ This Humacyte technology is

now undergoing clinical trials. More complex scaffold-based vascular grafts have also been developed, relying on micro-printing and electrospun nanofibers from natural and synthetic polymers to fabricate a tri-layered structure mimicking the layers in large vessels, with increased mechanical strength.²⁸⁴ These approaches rely on the rapid revascularization of the scaffold by host cells after implantation to form a new blood vessel. Loading scaffolds with cells prior to implantation has also been attempted,^{285,286} and can use various cells other than endothelial cells including endothelial precursor cells, ASCs, pericytes, and MSCs.²⁸⁷ Cells can also be incorporated as micro-tissue units into scaffolds in the form of spheroids.²⁸⁸ However, the use of cells in macrovessel tissue engineering has focused more on a scaffold-free approach. This relies on cell sheet engineering, where sheets of cultured dermal fibroblasts and their surrounding ECM are rolled into tubes which are then seeded with the patient's endothelial cells.²⁸⁹ This technology has since progressed to clinical trials as the Lifeline tissue-engineered blood vessel.^{289–291} In another alternate strategy, Campbell *et al.* have developed an intraperitoneal graft model where silastic tubing is implanted into the peritoneal cavity *in vivo*, leading to a foreign body reaction consisting of an inner collagen layer, middle myofibroblast layer and outer mesothelium which form tubular “vessels” comprised of autologous cells. These vessels have been successfully grafted into the circulatory system of the host animal where they were shown to remodel in response to the new environment and remain patent for up to 16 months in rabbits.^{292,293}

Bone tissue engineering

Significant research efforts have been made to tissue engineer both load-bearing and non load-bearing bone to meet the demands for alternatives to autografts or allografts, which have their inherent disadvantages and supply limitations. However, limited translation to clinical application has occurred to date.^{294,295} Bone tissue-engineering strategies generally involve a biomaterial scaffold of suitable mechanical strength with or without added cells and/or biomolecules to encourage bone growth. Vascularization has often been neglected in bone tissue engineering, but is increasingly recognized to play a role beyond simple cell survival and nutrient/waste exchange, as normal bone repair occurs in close association with blood vessels and angiogenic factors, particularly VEGF, play a role in initiating and promoting osteogenesis.²⁹⁶

Tissue-engineered constructs for bone should be osteoconductive to allow bone cells to adhere, proliferate, and migrate. A range of ceramics (e.g., β -tricalcium phosphate and hydroxyapatite) and polymers have been reported to meet this requirement and a number have been used as bone substitutes clinically. Slowly degrading polymers, such as PLA and PCL, have been widely investigated to produce tough porous scaffolds for bone tissue engineering. FDA-approved PCL-based scaffolds have been developed for bone tissue engineering (Osteopore International), and used clinically as burr plugs and sheets for orbital floor reconstruction in more than 1000 patients.^{95,297} Altering the surface topography of some of these more traditional bone substitutes, such as the coating of ceramic titanium dioxide scaffolds with nanoparticles made of the same material, may further augment their regenerative potential.²⁹⁸

Scaffolds which are osteoinductive have also been produced and shown to enhance bone growth. A wide range of natural biopolymers have been studied for bone tissue engineering, including collagen, gelatin, silk fibroin, chitosan, alginate, and hyaluronic acid.²⁹⁹ Among inorganic compounds, bioactive glasses composed of silica-containing calcium, sodium and phosphorous oxides have been termed “bioactive” because they can form strong bonds to hard and soft tissues *in vivo*.³⁰⁰ These materials have been marketed commercially as Bioglass and used clinically, primarily in nonload-bearing applications.

Composite materials are attractive as they can be used to control biodegradation and can overcome brittleness. This strategy mimics the composite structure of bone, being an inorganic–organic composite structure. Examples include nanocomposite structures combining collagen and calcium phosphate, as well as chitosan–gelatin and ceramic scaffolds.^{299,301} Suspensions or pastes of ceramic or composite materials may also be used in surgical repair or via injection to encourage bone growth for small-volume repairs.

In addition to the influence of the scaffold, the osteoinductive growth factors, bone morphogenic proteins (BMPs), may be used to enhance bone tissue growth. Other growth factors (e.g., TGF- β_1 , FGF-2, platelet-derived growth factor) may also enhance bone formation, as summarized by van Gaalen *et al.*³⁰⁰ Tissue engineering utilizing BMPs has progressed to a number of clinical trials, primarily in spinal surgery, showing some promising results.^{92,300} VEGF plays a dual role in angiogenesis and osteogenesis, and its encapsulation in PLGA scaffolds has been shown to increase both vascularization and bone formation.³⁰² However, the direct use of growth factors in a clinical setting will need to proceed with caution with particular attention to safety and optimizing delivery systems. Using cells that secrete osteoinductive and angiogenic growth factors may be another option. This includes cells such as MSCs, as well as endothelial cells, including endothelial progenitor cells, which have been shown to secrete BMPs and TGF- β s and contribute to bone healing.^{303,304} Furthermore, the addition of osteogenic cells, such as osteoprogenitor cells found in the bone marrow or periosteum, MSCs, and more recently iPSC-derived MSCs or osteogenic progenitors, particularly in addition to supportive cells and growth factors, may accelerate bone repair through direct tissue contribution but also ECM deposition and interaction with the host environment.^{295,296}

Cartilage tissue engineering

Tissue engineering of cartilage is relatively well developed as the problem is simplified by not requiring vascularization within the developing tissue. Several cell and tissue-engineering treatments for cartilage repair have been established clinically. However, clinical use is not widespread as yet due to limitations in efficacy, consistency, and applicability.³⁰⁵ Autologous chondrocyte implantation for articular cartilage repair has been approved by the FDA and implemented clinically (Carticel®, Genzyme Biosurgery, US).²⁹⁴ Although this procedure has shown good clinical outcomes, it is labor-intensive in the cell expansion and multi-stage procedure, and limited in the defect size that can be treated.^{306,307}

Biomaterial support structures may be used to treat larger cartilage defects, deliver cells, and provide critical mechanical support until the tissue is sufficiently developed. A possible timeline for cartilage repair using a biomaterial implant is

Fig. 16.29 A timeline for cartilage tissue engineering from *in vivo* implantation to formation of the final tissue. (From Palsson BO, Bhatia SN. Tissue Engineering. Upper Saddle River, NJ: Pearson Education, 2004.)

shown in the idealized schematic in Fig. 16.29. The 3D arrangement of chondrocytes is important to their function and the ECM synthesis required for tissue development, and this may be encouraged by suitable biomaterial scaffold design.^{69,308} Native articular cartilage is not isotropic but contains zones of different ECM and cell organization and function. Current research aims to develop biomaterial scaffolds which mimic this feature of cartilage more effectively to achieve engineered tissues with the normal zonal organization.^{305,309}

A range of biodegradable polymers, including PLGA, PCL, hyaluronan, gelatin, and collagen, have been used to produce scaffolds and microspheres to support chondrogenesis.^{82,306,308,310} Matrix-induced autologous chondrocyte implantation is similar in procedure to routine autologous chondrocyte implantation, but it relies on scaffold technology where cells are expanded and cultured on porcine collagen type I/III membranes prior to implantation.³¹¹ Hyalograft (a form of the biomaterial product Hyaff-11 from FIDIA Advanced Biopolymers, Italy) is a hyaluronic acid-based 3D scaffold product for cartilage tissue engineering that has also been used clinically.^{49,306}

The main cartilage tissue engineering approaches are the delivery of cells in a hydrogel or scaffold, the implantation of acellular scaffolds tailored to stimulate chondrogenesis, or scaffold-free techniques involving the culture and implantation of chondrogenic spheroids which may be derived from stem cells such as iPSCs.³¹² The physical microenvironment of the cells is important to tissue development, and can be manipulated during *in vitro* culture using forces such as gravity and hydrodynamic forces from the fluid motion to affect the quality and size of cartilage tissue formed (Fig. 16.30).^{308,313} A number of bioreactor designs have been devised to provide favorable *in vitro* growth conditions for chondrocytes.^{305,310} Other novel aspects being explored include 3D printing, including the use of BioPen technology where cells in an ECM carrier ink could be delivered through a pen nozzle, allowing the filling of small surgical defects as well as precise coverage over bone and cartilage surfaces.³¹⁴

Tissue engineering of other organs

Striking advances are being made in identifying, characterizing, and culturing various stem cells, in tailoring scaffolds

to maximize tissue assembly, and greater emphasis is now placed on the critical role of vascularization in supporting engineered tissue. With this integrated approach, there has been an exponential growth in tissue engineering studies in recent years, with a number of high profile clinical reports.^{315,316}

Using our models of intrinsic vascularization, we have been successful in generating a range of tissues including cardiac tissue from rat neonatal cardiomyocytes,¹⁶² human ASCs,³¹⁷ and human iPSCs.³¹⁸ The chamber has also been used for the implantation of pancreatic islets,³¹⁹ and liver progenitor cells.¹⁶⁵ We have also engineered tissue capable of secreting growth hormone after implantation of mouse pituitary stem

cells into a vascularized chamber in mice³²⁰ and restored thymus function in athymic rats after implantation of human thymic tissue in vascularized chambers as evidenced by the postoperative appearance of processed T cells in the blood and by the rejection of skin allografts.³²¹

Most recently, the field has placed particular interest in the use of extracellular matrix scaffolds derived from decellularized tissues and whole organs of various types, including human heart,³²² lungs,³²³ liver,³²⁴ and kidneys.³²⁵ Many pre-clinical studies have demonstrated the recellularization of these scaffolds with various cells including organ-specific cells and other stem cells, with cell attachment and organization into their native compartments to recapitulate tissue architecture. Many of these bioengineered tissues and organs have been implanted in small animal models, and several of these areas have been translated into clinical studies.

An early human clinical trial on organ tissue engineering was led by Atala *et al.* and focused on the bladder. A significant milestone was the report in 2006 that engineered bladder tissue showed promising outcomes in a clinical trial for cystoplasty reconstruction.^{326,327} Autologous cells from a bladder biopsy were seeded on to biodegradable scaffolds and grown *in vitro* prior to transplantation (Fig. 16.31). Bladder function was shown to improve and this was sustained up to 5 years. Atala provided an anecdotal note in 2014 that these patients continued to do well up to 11 years later.³²⁸ However, a recent Phase II trial by a separate group using the same protocol reported no improvement in bladder compliance or capacity, and serious adverse events such as bowel obstruction and/or bladder rupture in 4 out of 10 patients.³²⁹ Atala considers the disparity possibly to be due to a number of reasons. These include variability in patient cells, batch-to-batch manufacturing variability due to an individualized process, genetic variability, and lastly difference in the clinical spectrum of spina bifida patients in terms of their level of spinal cord pathology, bladder innervation, and functional disturbance.³²⁸ While efforts are being made to address these unique issues in regenerative medicine, it is worth remaining prudent and cautiously optimistic while we await the results of the next bladder trials before making any firm conclusions.

In 2008 Macchiarini *et al* reported the transplantation of the first bioengineered trachea in a human patient, based on

reseeding a decellularized tracheal graft with the patient's own epithelial cells and MSC-derived chondrocytes.³³⁰ A 5-year follow-up report noted that the graft remained patent, vascularized, and completely recellularized with normal function and no signs of rejection, although stenosis of the native trachea near the anastomosis required repeated endoluminal stenting.³³¹ This group has also developed a synthetic tracheal graft fabricated from nanocomposite polymer, which was reseeded with a patient's cells in a bioreactor prior to transplantation.³³² Transplantation of bioengineered trachea based on decellularized matrix has also been performed in a paediatric patient.³³³ However, these remain individual case studies and very much like with bladder tissue engineering, expanded clinical studies with long-term follow-up is required before these feats become an accepted treatment.

In 2014, a small pilot study of 4 patients with vaginal aplasia involved the transplantation of vaginal organs created from autologous epithelial and muscle cells obtained from a vulval biopsy and seeded in segments of Surgisis (decellularized porcine intestinal submucosa matrix).³³⁴ This technology could be useful not only for vaginal reconstructions but also for other soft tissue defects, although the lack of integrated vascularization will likely limit the use to thin grafts implanted into relatively well-vascularized sites.

Whilst clinical studies are still few and far between and fraught with technical challenges, we are gradually moving from thin flat tissues (skin, cornea) to tubular (trachea, blood vessels) and hollow viscus organs (bladder), and in the foreseeable future will likely progress to solid organs such as the kidney, heart or liver. Organ regeneration is the grail of tissue engineering, and with the advent of iPS cells this field offers a new direction in personalized organ repair – once the realm of science fiction, but now yielding incredible discoveries at a rapid pace.

Repair, grafting, and engineering of cartilage

Wei Liu and Yilin Cao

SYNOPSIS

- Cartilage is one of the most important tissue grafts in plastic surgery and is widely used in auricular reconstruction, rhinoplasty, and facial contouring.
- This chapter introduces the background knowledge and surgical skills required for harvesting cartilage graft and managing donor site tissues.
- Additionally, recent developments in engineered cartilage fabrication and their potential application in plastic surgery are described.

Introduction

Cartilage is a kind of connective tissue which is mainly composed of chondrocytes and their extracellular matrices (ECM) of type II collagen fibers, proteoglycans, and elastic fibers. According to its composition, cartilage can be classified into three types¹: (1) hyaline cartilage; (2) fibrocartilage; and (3) elastic cartilage. Fig. 17.1 shows the histology of the three types of cartilages.

Hyaline cartilage is the most common type of cartilage and can be found in costal, articular, tracheal, and nasal cartilage. With the exception of articular cartilage, the free surface of most hyaline cartilage is covered with perichondrium. In addition to collagen II, hyaline cartilage is rich in glycosaminoglycans and is thus characterized by its stiffness, that permits sustained compressional loading.

Fibrocartilage is composed of bundles of thick collagen fibers along with intervening unicellular islands of cartilage arranged in small chains. Because of this unique structure, fibrocartilage can provide high tensile strength and supporting function and is thus present in areas that are most subject to frequent stress, such as meniscus, intervertebral discs, symphyseal joints, and the joint portion of bone and

tendons/ligaments. In contrast to other cartilage, fibrocartilage also contains type I collagen. In addition, it has moderate amounts of proteoglycan but little glycosaminoglycans.

Elastic cartilage is characterized by its extremely high elasticity because of the presence of abundant amounts of elastic fibers. It is histologically similar to hyaline cartilage but contains many elastic fibers which form an elastic fiber network along with collagen fibers. This unique feature provides great flexibility so that elastic cartilage can withstand repeated bending. It is mainly found in the outer ear structure, and also in the larynx and epiglottis. It is also surrounded with perichondrium.

The perichondrium is a layer of dense irregular connective tissue that consists of two separate layers, an outer fibrous layer and an inner chondrogenic layer. Collagen fibers and fibroblasts constitute the fibrous layer. In contrast, the chondrogenic layer remains partially undifferentiated and is likely to contain mesenchymal stem cells and chondrogenic progenitor cells,^{2,3} which can play a role in cartilage repair and regeneration.

Cartilage is a unique tissue with low metabolic rate due to the sparsity of its cell population and its avascular structure. The glycolytic activity and oxygen consumption of cartilage approaches anaerobic condition and the tissue is nourished by tissue fluid diffusion. Because of this unique feature, cartilage graft is relatively easy to survive when being implanted. In terms of cartilage grafting, Sushruta Samhita in India probably is the first person to perform cartilage grafting in the form of a composite graft.^{4,5} Cartilage graft is widely used for repairing nasal or auricular defects as well as for reconstructing other tissues either as a pure cartilage graft or as a composite graft. According to surgical procedures, cartilage can be transferred either as a free graft or as a microvascular composite graft. Generally, autologous cartilage graft will not have metaplastic changes even being transferred to a different location.⁶ In addition, grafting of free perichondrial tissue is also a common procedure for cartilage reconstruction because

Fig. 17.1 Histology of (A) hyaline cartilage, (B) fibrocartilage, and (C) elastic cartilage (silver staining). (Courtesy of Dr. Roger C. Wagner, Prof. Emeritus of Biological Sciences at University of Delaware and Prof. Fred E. Hossler, East Tennessee State University.)

it has long been observed that perichondrium possesses the ability to regenerate cartilage.⁷

Autologous cartilage grafts and applications⁶

Although cartilage is considered as “immunologically privileged”, and allogeneic cartilage may serve as a potential graft,

autologous cartilage grafting remains the most applicable cartilage graft. Generally, common donor sites for harvesting autologous cartilage grafts include auricular, nasal, and rib cartilage.

Auricular cartilage graft

As an elastic cartilage, auricular cartilage is an ideal graft for transplantation and perhaps is the most versatile of all cartilage grafts because it can be easily fashioned and contoured into different shapes for various uses. Auricular cartilage can be harvested easily under local anesthesia and a significant portion of the concha can be removed without causing donor site deformity.⁶

However, in practice, harvesting of the entire conchal cartilage is likely to cause collapsed conchal bowl, cymba concha, and a horizontally short ear. To overcome this problem, Han *et al.* proposed the surgical procedure that involves: (1) using a postauricular incision to minimize visible scars; (2) harvesting the entire cymba concha and cavum concha separately, with at least 5 mm of the helical crus, leaving a lateral extension as a strut between them, as well as a 2-mm outer rim along the conchal wall; and (3) by using a tie-over bolster dressing that can serve as a mold for the conchal bowl. Fig. 17.2 presents the technique to avoid contour irregularity or deformity after harvesting the maximal amount of conchal cartilage graft.⁸

Auricular cartilage graft is often used as a framework for ear reconstruction or auricular deformity correction, as reported by Brent,⁹ Ono *et al.*,¹⁰ Firmin *et al.*,¹¹ and others. In addition, conchal cartilage can be used as a single-layered graft for nasal, tarsal, and nipple reconstruction.⁶

The other important application of auricular cartilage is to transfer as a composite chondrocutaneous graft for nasal reconstruction. How to manage the donor site of auricular composite graft aesthetically is important for its successful application. Singh and Bartlett have summarized several techniques to deal with the donor site of free auricular composite grafts according to different applications¹²:

- Technique 1: A composite graft that is less than 1 cm can be harvested from the root of the helix and the dog ear is run anteriorly toward the hairline with primary closure of the defect (Fig. 17.3).
- Technique 2: This is designed to close the donor site wound of the composite graft with cartilaginous base of 1–1.5 cm, which is usually needed to repair a wider defect of the alar rim (Fig. 17.4).
- Technique 3: To repair a nasal defect with short vertical dimension (height), the composite graft can be harvested from the anterior aspect of the helical root and the dog ear must be run superiorly and inferiorly. As shown in Fig. 17.5, this technique can provide adequate tissue for nasal reconstruction and an aesthetic closure without disturbing the size of the ear.
- Technique 4: For harvesting grafts with width of 1–1.2 cm from the base of the helix, the defect may be closed primarily by advancing the helical rim forward. The possible resulting overprojection of the ear might be addressed with a postauricular incision and a scaphomastoid suture to match the prominence with the contralateral ear (Fig. 17.6).

Fig. 17.2 The surgical technique for harvesting the maximal amount of conchal cartilage graft. **(A)** Markings. It was necessary to leave at least 2 mm of the superior outer rim along the conchal wall in order not to cause a noticeable change in the conchal bowl of the donor ear. Note the helical crus with its lateral extension between the cymba concha and cavum concha. **(B)** The entire unit of the cymba concha and cavum concha was removed separately, leaving at least 5 mm of the crus helicus with an extension to prevent collapsing. **(C)** There is almost no external evidence that the large conchal cartilage graft had been removed. **(D)** Two peanut cotton balls were placed into the interstices of the ear and sutured in place with through-and-through 4-0 nylon sutures, which were removed 5 days later. **(E)** The harvested cymba and cavum conchae were placed *in situ* to demonstrate their relationship with the intact helical crus and its lateral extension. **(F)** The surface area was 224.0 mm² at the cymba concha and 247.0 mm² at the cavum concha. (Reproduced from Han K, Kim J, Son D, et al. How to harvest the maximal amount of conchal cartilage grafts. *J Plast Reconstr Aesthet Surg.* 2008;61:1465–1471.)

Fig. 17.3 Technique 1: Harvest of a small composite graft (<1 cm) with primary closure by running the dog ear anteriorly into the hairline. This closure preserves contour of the ear. (*Reproduced from Singh DJ, Bartlett SP. Aesthetic management of the ear as a donor site. Plast Reconstr Surg. 2007;120:899–908.*)

Fig. 17.4 Technique 2: (A–C) A wider defect of the alar rim requires a larger composite graft from the helical base, as seen by the markings on the ear. (D,E) Closure of the defect is accomplished by running the dog ear anteriorly into the hair line and posteriorly into the triangular fossa. A full-thickness wedge of cartilage must be removed from the triangular fossa to prevent buckling of the ear. (*Reproduced from Singh DJ, Bartlett SP. Aesthetic management of the ear as a donor site. Plast Reconstr Surg. 2007;120:899–908.*)

Fig. 17.5 Technique 3: (A, B) The nasal defect is wide but short in its vertical dimension. This allows harvest from the anteroinferior helical rim. (C, D) Primary closure is achieved by running the dog ear superiorly and inferiorly. (Reproduced from Singh DJ, Bartlett SP. Aesthetic management of the ear as a donor site. *Plast Reconstr Surg.* 2007;120:899–908.)

- Technique 5: After harvesting composite graft wider than 1.5 cm from the base of helix, the closure of such a wound becomes more intricate. A simple helical advancement would result in significant distortion and overprojection (Fig. 17.7). To overcome this, a V-shaped wedge of skin is harvested, but a “half-star” pattern of cartilage at the apex of the V is taken (Fig. 17.8B–E). In addition, a postauricular incision with a scaphomastoid suture is needed. With these procedures, this technique can prevent cupping of the ear with closure (Fig. 17.8F).
- When an extended skin graft component is needed with the composite graft, the composite tissues can be taken either preauricularly or postauricularly, as demonstrated by the markings on Fig. 17.9.

The techniques described above provide simple methods to close the wounds of auricular chondrocutaneous composite grafts primarily with appreciable aesthetic outcome.¹² Other methods of rotational flap or skin graft have also been described in the literature.^{13,14} Importantly, the functional and aesthetic aspects should be well balanced for both the repair

site and donor site when a physician decides to harvest an auricular composite chondrocutaneous graft of a particular size and shape.

One concern for the clinical application of free auricular composite grafts is their limited size due to the lack of immediate blood supply after transplantation. In contrast, microvascularly transferred auricular composite grafts can overcome this limit and are particularly useful when repairing large nasal defects. Zhang *et al.* have recently reviewed their experiences of surgical treatment of large nasal defects with vascularized preauricular and helical rim flaps based on the superficial temporal vessels in 63 clinical cases. The repaired deformities include unilateral alar defect, alar and side wall defects, tip and columellar defects, entire lower third of the nose missing, and composite defects involving cheek and maxilla. The total flap survival rate reached 97%. The results demonstrate that such an approach, using vascularized preauricular and helical rim flaps, is a reliable method for reconstructing nasal defects.¹⁵ Fig. 17.10 demonstrates the surgical technique for repairing an alar lobule defect with vascularized helical rim composite tissue and preauricular skin.¹⁵

Fig. 17.6 Technique 4: (A, B) Inset of graft and aesthetic outcomes of nasal reconstruction and (C) the auricular donor site in comparison with (D) the contralateral ear. (Reproduced from Singh DJ, Bartlett SP. Aesthetic management of the ear as a donor site. *Plast Reconstr Surg.* 2007;120:899–908.)

Fig. 17.7 (A–C) With harvest of a small (1–1.2 cm) composite graft, closure can be achieved by helical rim advancement. However, overprojection of the ear may result, as seen in this series of photographs. (Reproduced from Singh DJ, Bartlett SP. Aesthetic management of the ear as a donor site. *Plast Reconstr Surg.* 2007;120:899–908.)

Fig. 17.8 Technique 5: (A,B) This nasal defect requires a larger composite graft with a width of 1.8 cm. The harvest site on the auricle is demonstrated by the purple lines. (C–E) To overcome distortion and overprojection resulting from tissue harvest, closure for this size auricular defect involves a V-shaped wedge of skin and a half-star pattern of cartilage excision at the apex of the V. The solid lines indicate skin incision and the dotted star pattern demonstrates cartilaginous incisions. In addition, a postauricular incision with a scaphomastoid suture is performed. (F) This technique of wound closure prevents the cupping of the ear and relatively normal shape and projection of the ear are maintained after the closure. (Modified from Singh DJ, Bartlett SP. Aesthetic management of the ear as a donor site. *Plast Reconstr Surg.* 2007;120:899–908.)

Fig. 17.9 Occasionally, an extended skin graft is needed in addition to the composite graft for reconstruction of nasal defects. (A) The solid lines indicate skin incisions and the dotted line indicates a cartilaginous incision. (B) The solid lines represent the harvest of a postauricular full-thickness skin graft. (Reproduced from Singh DJ, Bartlett SP. Aesthetic management of the ear as a donor site. *Plast Reconstr Surg.* 2007;120:899–908.)

Fig. 17.10 A 17-year-old female with a deformity of the left alar lobule after laser treatment of a hemangioma. An ipsilateral reverse-flow flap consisting of both the helical rim and the preauricular skin (2.2×1.8 cm) was used. The anastomosis was made to the proximal end of the superficial temporal vessels by means of 11-cm vascular grafts from the descending branch of the lateral circumflex vessels. Extended applications of vascularized preauricular and helical rim flaps in reconstruction of nasal defects. *Plast Reconstr Surg.* 2008;121:1589–1597.)

Nasal cartilage graft

Although limited in its available amount, nasal cartilage has been employed as a composite chondromucosal graft for eyelid reconstruction. Septal cartilage is an important source of nasal cartilage graft. As reported by Murrell, the septal cartilage can be accessed via a hemitransfixion incision with dissection around the caudal margin of the quadrangular cartilage. After both sides of mucoperichondrium are raised, the septal cartilage can be harvested.¹⁶ Importantly, as shown in Fig. 17.11, an L-shaped septal strut should be preserved to give nasal support and avoid nasal collapse.^{6,16} Nevertheless, the amount of L-shaped strut cartilage necessary to provide good support can vary greatly depending on the strength, thickness, and dimensions of the nasal septum and other nasal tissues (i.e., upper lateral cartilages, lower lateral cartilages, nasal bones).¹⁶ As early as 1962, Millard published his work of repairing eyelid defects with a chondromucosal graft harvested from nasal septum. Later, Mustardé also described the technique in the book *Repair and Reconstruction in the Orbital Region*.⁶

The other region available for harvesting nasal chondromucosal graft is the upper lateral nasal cartilage, as reported by Tessier in 1979.⁶ In clinical practice, repairing a large defect of the upper eyelid is always a challenge. Scuderi and colleagues have developed a surgical technique to address such a concern. In their report, a pedicled nasal chondromucosal flap was designed along the lateral nasal wall based on the terminal branch of the dorsal nasal artery. The flap includes the subcutaneous tissues down to the periosteum and the cranial portion of the upper lateral cartilage. It can be harvested either unilaterally or contralaterally and a skin graft is applied for cutaneous coverage. In their reported 15 patients, the flap was viable in every patient and satisfactory functional recovery was achieved, indicating that this one-stage procedure can reconstruct a thin and mobile eyelid.¹⁷

Fig. 17.12 demonstrates its design and surgical procedure as well as its clinical outcome.¹⁷ In addition to eyelid repair, septal cartilage graft has been used for dorsal augmentation,¹⁶ tracheal repair,¹⁸ and extended septal graft for controlling the projection shape of nose tip.¹⁹

Fig. 17.11 Harvest of nasal septal cartilage graft. It is important to keep the L-shaped strut cartilage (shown in stripes) to provide nasal support. The area of septum that attaches to the upper lateral cartilages should also be preserved. Generally, nonsupportive quadrangular cartilage, which is pictured posterior to the dashed vertical line, can be harvested freely. (Reproduced and modified from Murrell GL. Dorsal augmentation with septal cartilage. *Semin Plast Surg.* 2008;22:124–135.)

Rib cartilage graft

Costal cartilage may serve as the best donor site for cartilage graft in terms of available tissue amount and mechanical strength. The autologous rib cartilage can be virtually contoured into any desired shape and it can retain form and bulk after implantation if basic surgical principles are followed.⁶ The costal cartilage graft is often used as a cartilage framework for total ear reconstruction. Tanzer,²⁰ Thomson *et al.*,²¹ and Brent²² have respectively described the technique to harvest costal cartilage to construct auricular framework. In the procedure, the synchondrosis of the sixth and seventh cartilages as well as the eighth costal cartilage is harvested, usually along with the perichondrium.^{20–23} In contrast, Nagata's method for total auricular reconstruction requires the harvest of four costal cartilages in the first-stage operation and one or two costal cartilages for the second-stage operation.^{24–28} Fig. 17.13 is a schematic illustration of the harvest of rib cartilage designed for ear reconstruction or chin contouring.²⁹

In clinical practice, harvest of costal cartilage can be associated with donor site morbidity. Uppal *et al.* have reported their investigation on morbidity associated with the harvest of costal cartilage in 42 patients who underwent ear reconstruction. The commonest complaints included pain and clicking of the chest wall, which usually peaked in the first

week postsurgery and gradually diminished over 3 months. The other problems were scar and chest wall deformity.³⁰ Among them, the most challenging problems are pneumothorax during the surgical procedure and resulting abnormal chest wall contour. This is particularly true for Nagata's

Fig. 17.13 Donor site for costal cartilage grafts in auricular framework and chin graft construction. E, ear base block; H, helix; C1, chin graft, first layer; C2, chin graft, second layer. (Reproduced and modified from Brent B. *Repair and grafting of cartilage and perichondrium.* In: McCarthy JC (ed). *Plastic Surgery.* Philadelphia: WB Saunders; 1990:559–582.)

method, which requires more and extra cartilage grafts for auricular reconstruction.^{24–28}

To address this concern, Kawanabe and Nagata developed a new method for harvesting rib cartilage to avoid intra-operative and postoperative complications and problems. In this modified procedure, the costal cartilages were harvested *en bloc* with the perichondrium left completely intact at the donor site. In addition, after the fabrication of the auricular cartilage frame, the remaining costal cartilage was cut into small blocks that acted as spacers to fill the dead space formed in the perichondrial pocket. The retained perichondrium not only helps to avoid the injury of pleura, but may also promote cartilage regeneration because of the presence of chondrogenic stem cells.^{2,3} In an investigation of 270 cases of total auricular reconstruction performed using Nagata's method and the new method of rib cartilage harvesting, the incidence of infection and pneumothorax was reduced to less than 1%. More importantly, there were no postoperative chest wall deformities when costal cartilage was harvested with this new technique.³¹ Interestingly, a follow-up study revealed that returned hyaline cartilages were mixed with fibrocartilage with visible margins at 6 months postsurgery. Twelve months after the first-stage operation, homogeneous hyaline cartilage was observed histologically, and the regenerated cartilages were similar to native costal cartilages in their hardness, which enabled the second harvest.³² Fig. 17.14 gives a schematic illustration of harvesting costal cartilage with the new method of retaining perichondrium and returning the remaining costal cartilage to the donor site.³¹

Modification of previously established methods of making auricular framework is also considered as an alternative option to avoid harvesting extra cartilage and thus help to prevent chest wall deformity. As an example, Chin *et al.* recently reported several modifications of auricular framework which required less cartilage graft and meanwhile could also generate individualized and harmonious ear frameworks to meet the need for satisfactory three-dimensional (3D) outline of a reconstructed auricle.³³ The framework may consist of the helix, the base frame, the Y-shaped antihelical complex, and the tragus attached to an additional cartilaginous cube depending on individualized need (Fig. 17.15). In addition, bone cement is used as the support material during the ear elevation stage, and therefore extracostal cartilage harvesting became unnecessary.³⁴ Fig. 17.16 demonstrates the clinical outcome of reconstructed ear with modified frameworks based on the individualized 3D auricle structures.³³

In addition to auricular reconstruction, rib cartilage graft also has other applications, including reconstruction of significant saddle-nose deformity,³⁵ treatment of maxillonasal dysplasia (Binder's syndrome),³⁶ nipple reconstruction,³⁷ for septorhinoplasty,³⁸ and in tracheal reconstruction.³⁹

Autologous perichondrial graft

In 1959, Lester first reported the potential of neocartilage formation by transplanted perichondrium.⁴⁰ This phenomenon has also been observed by others.^{41–44} Despite the enthusiasm and optimism derived from the pioneering observations, the clinical application of perichondrial grafts for cartilage regeneration remains limited to certain conditions, such as the reconstruction of degenerated knee joint cartilages. The

potential causes limiting its application include the technique of harvest, the oxygenation of the recipient bed, and the presence of chondroprogenitors at the recipient site, which can all have an influence on the composition of the new tissue.⁴⁵ With proper microenvironments, perichondrium-mediated cartilage regeneration remains possible, as revealed by experimental studies. For example, Sari *et al.* reported neocartilage formation in a folded-ear perichondrium at 6 weeks postimplantation under the abdominal muscle in rabbit.⁴⁵

One of the major clinical applications is for joint repair. As early as 1975, Engkvist *et al.* reported a pilot experimental study of regenerating articular cartilage of cavitas glenoidalis by transplanting ear perichondrium in a rabbit model. Further, clinical trials were formed in 5 cases of arthritis patients. After removal of the degenerated cartilage, rib perichondrium was grafted and articular cartilage regeneration took place.⁴⁶ Following the initial trials, there were some reports of the application of perichondrium graft for clinical repair of human knee joint articular cartilage,^{47,48} but there were few on repairing articular cartilage of human digits.⁴⁹ Instead, transplantation of costal osteochondral grafts became the major tissue graft for functional restoration of injured digital articular cartilage.^{50,51}

The other important clinical application might be nasal reconstruction either as a perichondrium graft or as a perichondrocutaneous graft. Recently, Boccieri and Marianetti reported the application of perichondrium graft for nasal surgery. Because of its thinness and malleability, perichondrium is particularly suitable for covering every part of the cartilaginous graft, and is easy to fold into various layers if greater thickness is required in filling certain areas and therefore is commonly used in secondary rhinoplasty.^{52,53} Fig. 17.17 demonstrates the surgical procedure of nasal tip reconstruction with auricular perichondrium.⁵²

In addition, perichondrocutaneous graft is a common graft type. Brent and Ott reported the graft and proposed its application in reconstructive facial surgery in 1978.⁵⁴ The donor source for the graft should be restricted to concha in order to prevent deformity.⁶ This graft has wide applications. It has been reported to be used for facial reconstruction,^{55,56} for reconstruction of nasal defect,^{57,58} for auricular defect repair,⁵⁹ and repairing ectropion.⁶⁰ Overall, although both perichondrium and perichondrocutaneous grafts have been widely used for clinical repair of tissue defect, there remains no solid clinical evidence to support the theory that transplanted perichondrium is able to regenerate a significant amount of cartilage tissue.

Cartilage engineering

Introduction and basic principle

Cartilage probably is one of the most commonly used tissue grafts in plastic surgery and has been employed in auricular reconstruction, rhinoplasty, and other surgical procedures, as described above. However, autologous cartilage graft is limited in its available amount and tissue harvest may cause donor site morbidity.

Tissue engineering is a new biotechnology developed from the late 1980s and early 1990s, which aims to repair and regenerate human tissue via an engineering approach

Fig. 17.14 (A) Schematic illustration of the new method of costal cartilage harvest. (Top, left) The muscular fascia of the rectus abdominis muscle and the external oblique muscle are exposed. (Top, center) A longitudinal incision is made between the rectus abdominis muscle and the external oblique muscle with delicate dissecting scissors. (Top, right) The perichondrium is completely exposed. (Center, left) The line of incision is marked in the center of the costal cartilage, and, taking special care not to injure or damage the cartilage, the incision is made with a scalpel. (Center, center) The anterior surface of the perichondrium is first undermined with an elevator. (Center, right) The undermining of the posterior surface of the perichondrium requires extreme caution because the risk of pneumothorax exists; therefore, the tip of the elevator is placed on the cartilage or must face the cartilage to avoid accidental puncture of the thoracic wall. The approximately 1 cm of periosteum at the costochondral junction is undermined for easier harvest of the costal cartilage. (Bottom, left) A Doyen rib raspatory is inserted underneath the undermined costal cartilage between the cartilage and the perichondrium at the costochondral junction. The costal cartilage is excised with a scalpel and the costochondral junction is to be left behind at the donor site. (Bottom, center) Harvesting of the costal cartilages is easier if the sixth and seventh costal cartilages are harvested from the side of the costochondral junction instead of the sternal side. (Bottom, right) The appearance of the donor site immediately after the harvest of the costal cartilages. The perichondrium is left completely intact at the donor site.

Avoidance and prevention of intraoperative and postoperative complications and problems. *Plast Reconstr Surg.* 2006;117:2011–2018.)

to produce autologous tissue. Actually, cartilage is closely related to the development of tissue engineering because it was used as a tissue target to prove the basic principle.^{61,62} Interestingly, the success in the engineering of human ear-shaped cartilage in a nude mouse model vividly revealed that this tissue-engineering technique has great potential in plastic surgery for tissue repair and reconstruction.⁶³

Fig. 17.15 The modified rib cartilage framework may contain these parts to provide prominent structures. From left to right, the helix, the base frame, the Y-shaped antihelical complex, and the tragus attached to an additional cartilaginous cube. (Reproduced from Chin W, Zhang R, Zhang Q, et al. Modifications of three-dimensional costal cartilage framework grafting in auricular reconstruction for microtia. *Plast Reconstr Surg.* 2009;124:1940–1946.)

As outlined by Stock and Vacanti,⁶⁴ the basic concept of tissue engineering includes a scaffold that provides an architecture on which seeded cells can organize and develop into the desired organ or tissue prior to implantation. The scaffold provides an initial biomechanical profile for the replacement tissue until the cells produce an adequate ECM. During the formation, deposition, and organization of the newly generated matrix, the scaffold is either degraded or metabolized, eventually leading to a vital organ or tissue that restores, maintains, or improves tissue function.

Generally, the tissue-engineering process involves three major components: (1) seed cells: the component for matrix production, deposition, and tissue formation; (2) scaffold: the substance that provides a 3D construct for cells to reside, proliferate, and produce matrix; (3) tissue formation environment: after being seeded on the scaffold, cells start to grow and produce and deposit ECMs on the scaffold. In a proper environment, with gradual degradation of the scaffold, cell proliferation, matrix production, and proper tissue remodeling, an engineered tissue gradually forms and becomes mature.

In the past 20 years, tremendous progress has been made in basic and applied research of cartilage engineering, including the search for different biomaterials as scaffolds, seeking different cell sources and chondrogenic induction of stem cells as well as advances in the techniques of cartilage tissue formation, such as *in vitro* reconstruction of cartilage tissue. Among

them, some have already revealed the great potential in plastic surgery, for example, auricular reconstruction, rhinoplasty, and facial contouring. The following gives a few examples of generation techniques and the results of engineered cartilages that may potentially be used for cartilage repair and reconstruction.

Engineering of auricular cartilage

An important achievement in cartilage engineering research is the development of the technique that enables generation of a human ear-shaped cartilage, because it vividly reveals

the application potential in plastic surgery. The procedure is described below to provide an example of translational research of cartilage engineering.⁶³

To generate a human ear-shaped cartilage, selection of seed cell, scaffold materials, and an animal model should be determined according to the principle. In this study, chondrocytes derived from calf cartilage, polyglycolic acid (PGA), unwoven fibers, and a nude mouse model served as the basic components to construct the cartilage.

To isolate the cells, cartilage fragments were first harvested from the articular surface of glenohumeral and humeroulnar joints and then subjected to collagenase digestion (3 mg/mL)

Fig. 17.17 (A) Reconstruction of the nasal tip with lateral crural and shield grafts (Sheen-type) harvested from the cartilage of the auricular concha. (B) Graft of the perichondrium stretched over and secured to cartilaginous grafts to make the contours smooth and disguise tip grafts. (C) Lateral view of the same graft. (D) Schematic illustration of the perichondrium graft positioning and fixation. The presence of numerous grafts inevitably leads to sharp ridges and irregularities in the cartilaginous contour that can be eliminated by means of the perichondrium graft. (Modified from Boccieri A, Marianetti TM. Perichondrium graft: harvesting and indications in nasal surgery. *J Craniofac Surg.* 2010;21:40–44.)

in culture medium at 37°C for 12–18 hours. The resulting tissue digestion solution was filtered and centrifuged to collect the chondrocytes and the cells were expanded *in vitro*.

To prepare the scaffold for the human ear shape, the ear of a 3-year-old child was cast using alginate as the impression material, and then a final cast of plaster was fashioned from the alginate impression. Using the plaster cast as a mold, PGA nonwoven mesh in about 100 μm thickness was coated with 1% (w/v) solution of polylactic acid (PLA) in methylene chloride. Following immersion, the fabric was removed and shaped into the form of a human ear using the plaster prosthetic mold.

To prepare a cell–scaffold construct, the ear-shaped scaffold was placed in a culture dish and seeded with 3 mL of chondrocyte suspension (1.5×10^8 cells) and placed in an incubator for 4 hours to allow seeded cells to attach on the scaffold and then culture medium (Hamm's F-12 supplemented with 10% fetal calf serum, 5 $\mu\text{g}/\text{mL}$ ascorbic acid, 292 $\mu\text{g}/\text{mL}$ L-glutamine, 100 U/mL penicillin, and 100 $\mu\text{g}/\text{mL}$ streptomycin) was added, and the construct was incubated *in vitro* at 37°C in 5% CO_2 for 1 week. As shown, the cell-seeded construct could maintain a good ear shape (Fig. 17.18A) and scanning electron microscope revealed good cell attachment on the scaffold and matrix production (Fig. 17.18B).

Fig. 17.18 Chondrocytes seeded on to the polymer ear mold *in vitro*. (A) Gross appearance of the ear polymer mold seeded with chondrocytes (1.5×10^6). (B) Scanning electron micrograph showing adherence of chondrocytes to polyglycolic acid device before implantation. (Reproduced from Cao Y, Vacanti JP, Paige KT, et al. Transplantation of chondrocytes utilizing a polymer-cell construct to produce tissue-engineered cartilage in the shape of a human ear. *Plast Reconstr Surg.* 1997;100:297–302.)

After 1 week of *in vitro* culture, the cell-scaffold construct was implanted into the subcutaneous tissue of a nude mouse with the support of an external stent outside the skin to keep the shape (Fig. 17.19). As shown in Fig. 17.20, an ear cartilage structure is formed with the 3D shape that is almost identical to that of a human ear after 12 weeks of *in vivo* implantation. To verify the formation of engineered ear cartilage, tissues were harvested and subcutaneous tissues were stripped and the resulting gross view and histology confirmed a well-formed ear-shaped cartilage (Fig. 17.21). Through this pioneering study, the result provides an example of how to translate cartilage engineering research to plastic surgery application, particularly for engineered auricular reconstruction.⁶³

To explore the possibility of translating this technique to clinical application, a technique of *in vitro* engineering of human ear-shaped cartilage was developed with the assistance of computer-aided design (CAD) and computer-aided manufacture (CAM) technologies.⁶⁵

To proceed, computed tomography was employed to scan a patient's normal ear to collect the geometric data; the information was then processed by a CAD system to generate both positive and negative image data of the normal ear. The

resultant data were then input into a CAM system to print a mold with 3D structure of a normal ear in half size. Then, PGA unwoven fibers were inserted into the mold and coated with 0.3% PLA solution, thus generating a relatively solid ear-shaped scaffold material. The resulting scaffold was laser-scanned to generate a 3D image, which could be digitally compared with the original ear 3D image to analyze the similarity in 3D structure. As revealed in Fig. 17.22, the resulting ear-shaped scaffold achieved a similarity level of above 97% compared to the positive mold of original ear shape, indicating that the mold fabricated by CAD/CAM can fabricate a scaffold accurately into an ear shape that is mirror-symmetrical to the normal ear.

Afterwards, a total of 50×10^6 cells in 1 mL volume were evenly seeded on to the ear-shaped scaffold and cultured *in vitro* with medium change at regular time intervals. Interestingly, a human ear cartilage could be generated *in vitro* after 12 weeks of culture with good elasticity (Fig. 17.23). The engineered cartilage also revealed relatively mature histological structure of cartilage with lacuna structure formation and strong staining for Safranin-O and collagen II, as shown in Fig. 17.24. More importantly, the human ear-shaped cartilage formed *in vitro* could reach a morphological similarity of 82.6% to the positive ear mold, indicating that this technique not only can generate cartilage tissue *in vitro* but is also able

Fig. 17.19 An external stent was fixed on the outside skin of the polymer ear implant to maintain polymer mold shape (A) and the view of an external stent (B). (Reproduced from Cao Y, Vacanti JP, Paige KT, et al. Transplantation of chondrocytes utilizing a polymer-cell construct to produce tissue-engineered cartilage in the shape of a human ear. *Plast Reconstr Surg.* 1997;100:297–302.)

Fig. 17.20 (A–E) Gross appearance of the constructs 12 weeks after subcutaneous implantation into nude mice. Note the three-dimensional shape that is almost identical to that of a human ear. (Reproduced from Cao Y, Vacanti JP, Paige KT, et al. to maintain a designed 3D tissue structure (see Fig. 17.23).⁶⁵ Currently, continuous effort is being made in our center to study the fate of the *in vitro*-engineered ear-shaped cartilage after *in vivo* implantation and the progress in this area is expected to pave the way for the eventual clinical application of engineered human ear-shaped cartilage.

One of the unique properties of human ear cartilage is its excellent elasticity and flexibility that allow for torsion

and bending without causing a fracture. Mimicking such mechanical properties of the native tissue should also be an important consideration for engineering ear-shaped cartilage and its application. In 2005, Xu *et al.* reported a new method of generating flexible auricular cartilage.⁶⁶ In their study, auricular chondrocytes were isolated from swine ear cartilage by enzyme digestion and fibrin polymer was used as the scaffold. In addition, auricular perichondrium was

Fig. 17.23 Shape evaluation of the ear-shaped constructs. The scaffold shows an accurate ear-like structure (A) with a high similarity level compared to the positive mold (E). All the cell scaffold constructs largely maintain their original ear-like structures at 4 weeks (B), 8 weeks (C), and 12 weeks (D). Quantitative analysis shows over 84% shape similarity in all the samples (F–H) compared to the positive mold. (Reproduced from Liu Y, Zhang L, Zhou G, et al. *In vitro engineering of human ear-shaped cartilage assisted with CAD/CAM technology*. *Biomaterials*. 2010;31:2176–2183.)

Fig. 17.24 Histological examinations of the *in vitro* ear-shaped constructs. At 4 weeks, the constructs form heterogeneous cartilage-like tissue along with undegraded polyglycolic acid fibers (**A, D, G**). With prolonged culture time, the histological structure of the constructs gradually becomes compact, accompanied by increased numbers of lacuna structures at 8 weeks (**B, E, H**). Homogeneous cartilage with abundant extracellular matrix and mature lacunae is observed at 12 weeks (**C, F, I**) with no visible scaffold residuals in the constructs. The black arrows indicate the undegraded polyglycolic acid fibers. Scale bar = 100 μ m. (Reproduced from Liu Y, Zhang L, Zhou G, et al. *In vitro* engineering of human ear-shaped cartilage assisted with CAD/CAM technology. *Biomaterials*. 2010;31:2176–2183.)

harvested and lyophilized. During the engineering process, equal volumes of both the chondrocyte fibrinogen suspension and the thrombin solution were mixed together to give rise to a chondrocyte–fibrin polymer suspension. The suspension was then placed into an ear-shaped well made from bone wax to allow for polymerization. To produce a flexible cartilage, the polymerized chondrocyte–fibrin construct was sandwiched between two layers of lyophilized swine perichondrium to form a trilayer, ear-shaped construct and then implanted into athymic mice subcutaneously. As a control, chondrocyte–fibrin construct without perichondrium was implanted as well. At 12 weeks of implantation, engineered cartilaginous tissue was formed in both the experimental and control groups.

Importantly, engineered cartilage laminated with perichondrium exhibited mechanical properties similar to those of the native swine ear, and could tolerate severe torsion and bending without fracture, although the 3D structure remains

to be improved. Histology also revealed good integration between the engineered cartilage and lyophilized perichondrium (**Fig. 17.25**). In contrast, the engineered cartilage of the control group became fractured after the test of torsion and bending. The result of this study indicates that lamination with lyophilized perichondrium is a reliable method of conferring elastic-like flexibility to an engineered ear cartilage. In the future, selection of a proper solid scaffold may help to control the precise and detailed structure better in order to generate flexible auricular cartilage with better 3D structure.⁶⁶

In addition to the experimental studies that employed animal chondrocytes, human chondrocytes have also been investigated for their ability to form engineered cartilage. Kamil *et al.* reported a comparative study of normal chondrocytes and microtia chondrocytes from patients and the results showed their similar abilities in cell proliferation and cartilage tissue formation, indicating that cartilage derived from

Fig. 17.25 (A, B) Gross mechanical testing of the ear-shaped framework at 12 weeks after insertion demonstrates a continued high degree of flexibility. (C) After mechanical testing, the framework easily recovers its initial shape. (D) Hematoxylin and eosin staining of flexible tissue-engineered cartilage (original magnification $\times 100$; bar = 100 μm), demonstrating the tight adherence at the interface between neocartilage and the lyophilized swine perichondrium laminate (arrows indicate interface). microtia patients may potentially serve as the cell source to engineer human auricular cartilage.⁶⁷

Interestingly, Yanaga *et al.* reported a clinical trial of auricular reconstruction with fabricated human cartilage. In this trial, chondrocytes isolated from the cartilage remnant of microtia patients were cultured *in vitro* using a multilayer culture method, then the expanded cells along with their produced gelatinous chondroid matrices were collected into a syringe in the cell density of $0.5\text{--}1 \times 10^7$ cells per mL. Afterwards, 40–73 mL of cells/gelatinous matrices was injected into a subcutaneous pocket on the fascia of a patient's lower abdomen using a 16-gauge indwelling needle in order to generate an engineered cartilage block which could be sculptured into an auricular framework (Fig. 17.26). The results showed that a large piece of elastic cartilage was formed at the abdominal environment at 6 months postimplantation, which was also verified by histology examination. Importantly, this engineered cartilage block provides sufficient cartilage to create an ear framework. Furthermore, the framework could well support the reconstructed auricle without obvious absorption after being implanted for several years (see Fig. 17.26). This preliminary study provides important supporting evidence for the future clinical application of engineered auricular reconstruction.⁶⁸

Engineered cartilage for rhinoplasty and facial contouring

In addition to auricular reconstruction, rhinoplasty is another area where tissue-engineered cartilage may potentially be applied clinically. In contrast to auricular reconstruction, injectable cartilage is an important physical form for transplanting engineered cartilage.

In the early stage of tissue engineering research, injectable cartilage was employed to explore the feasibility of cartilage engineering using slowly polymerizing calcium alginate gels⁶⁹ or Pluronic gel,⁷⁰ amongst others. In recently published studies, human chondrocytes have also been confirmed to be able to form injectable cartilage using different injectable scaffolds.^{71,72}

Although most engineered injectable cartilage research remains at the experimental stage using either animal cells or an animal model, there are a few reports of the clinical application of injectable cartilage.^{73,74} Yanaga *et al.* reported a clinical trial of injecting cultured autologous chondrocytes for nasal augmentation. First, a piece of cartilage was harvested from auricular concha to extract chondrocytes and the cells were expanded *in vitro* into a gel-type cell-containing mass. Then, a subperiosteal skin pocket was created on the nasal dorsum

Fig. 17.26 Engineering of human cartilage block for auricular reconstruction.

(A) Injection of cultured chondrocytes subcutaneously. **(B)** Formation of engineered cartilage block with good elasticity. **(C)** Histological verification of engineered elastic cartilage. **(D)** An ear framework, sculptured from the engineered neocartilage block. **(E)** A 9-year-old boy with microtia before operation. **(F)** 2 years after auricular reconstruction with engineered framework. (Modified from Yanaga H, Imai K, Fujimoto T, et al. Generating ears from cultured autologous auricular chondrocytes by using two-stage implantation in treatment of microtia. *Plast Reconstr Surg.* 2009;124:817–825.)

of the patients and the chondrocytes were transplanted within a gel mass and the wound was closed. The implantation site was fixed with splint and tape for 3 weeks. Biopsy of injected tissue confirmed the formation of engineered cartilage after 1 month of implantation.

The procedure was applied in 8 patients for primary nasal augmentation or to correct a deformity resulting from silicone implant exposure or deviation. The patients were followed up for 6 months to 2 years and injected cartilage

could maintain its shape without resorption.⁷³ Later the same group further reported clinical trials in 32 patients for both nasal augmentation and facial contouring, with excellent clinical evaluation results and patient satisfaction in most cases.⁷⁴ Fig. 17.27 demonstrates the clinical outcome of injected cartilage for nasal augmentation. Additionally, the authors used injected autologous chondrocytes for chin augmentation and to correct temporal and forehead depressed deformity.^{73,74}

Fig. 17.27 A 35-year-old woman received injected cartilage to correct saddle-nose deformity. (A–C) Preoperative views. The autologous cultured auricular chondrocytes were grafted to the nasal dorsum. (D–F) Postoperative views after 34 months. The projection radix is higher than before grafting. The shape and contours of the nasal dorsum have aesthetically improved. Good contours have been maintained, and there has been no absorption of the grafted chondrocytes. (Reproduced from Yanaga H, Yanaga K, Imai K, et al. *Clinical application of cultured autologous human auricular chondrocytes with autologous serum for craniofacial or nasal augmentation and repair*. *Plast Reconstr Surg*. 2006;117:2019–2030.)

In addition to injectable cartilage, *in vivo*-engineered cartilage may potentially be used for nasal reconstruction. For example, Farhadi *et al.* reported the engineering of human nasal cartilage. In the study, chondrocytes were isolated from nasal septum and seeded onto nonwoven meshes of esterified hyaluronan (Hyaff-11). The cell-scaffold construct was cultured *in vitro* for 2 or 4 weeks and then implanted into nude mouse. The results showed that the cartilage was well formed after 2 weeks of *in vivo* implantation and the engineered cartilage exhibited good mechanical property.⁷⁵ Similar results were also reported in another study.⁷⁶ With enhanced mechanical strength, these *in vivo*-engineered cartilages may provide the autologous cartilage grafts potentially for septum or nasal alar reconstruction or nasal augmentation. *In vitro* engineering of cartilage with a nasal tip has been reported many years ago, aiming for nasal reconstruction with specifically shape-designed cartilage,⁷⁷ but its relatively weak mechanical strength might prohibit *in vitro*-engineered cartilage from immediate transplantation in nasal reconstruction.

Engineered cartilage for joint cartilage repair and reconstruction

Engineered cartilage may also serve as a composite graft to repair or reconstruct articular cartilage. There are two potential targets: temporomandibular joint (TMJ) and digital joints. In 2001, Weng *et al.* reported a preliminary study of mandible condylar reconstruction with tissue-engineered composites of bone and cartilage. In the study, scaffold of PLA-coated PGA was molded into the shape of human mandible condyle and respectively seeded with osteoblasts and chondrocytes followed by *in vivo* implantation in nude mouse. After 12 weeks, a condyle-shaped bone tissue was well formed with articular cartilage on the surface and histology confirmed the formation of trabecular bone and hyaline cartilage, suggesting a potential approach for clinical TMJ reconstruction.⁷⁸ In addition, engineered cartilage was proposed for TMJ disc reconstruction to potentially restore TMJ function.⁷⁹

Cartilage presents as the major tissue component in interphalangeal joints or metacarpophalangeal joints and plays an important functional role. As early as 1999, Isogai *et al.* reported a preliminary study on constructing small phalanges and the whole joints using a tissue-engineering approach.⁸⁰ The approach included the use of PLA or PGA as the scaffold and fresh bovine periosteum was harvested to wrap around the scaffold for bone engineering. Additionally, chondrocytes and tenocytes were seeded on the scaffold to form articular cartilage and associated tendon tissue. The results showed that a preliminary composite tissue formed with the shape and dimensions of human phalanges as well as the joints.⁸⁰ A study with much larger sample size was also performed to engineer composite tissue of human phalanges and a small joint, with successful results.⁸¹ Although these studies were preliminary, the results revealed the promise of the future application of engineered cartilage in joint reconstruction.

Future directions

Despite a few preliminary clinical trials of engineered cartilages in auricular and nasal reconstruction, there remains much to do in both basic and applied research prior to true

translation of cartilage research to clinical application. To fulfill the goal, the following areas may represent future directions.

Stem cell-based cartilage engineering

Although both auricular and nasal cartilages have been used as the sources to extract chondrocytes, the available tissue amounts are limited. Although more tissue volume can be harvested from rib cartilage, the amount of cells that can be harvested is limited due to low cellular density. Stem cells, particularly adult stem cells, have become an alternative cell source because of their multidifferentiation potential (including chondrogenic) and strong proliferation capability.

The adult mesenchymal stem cells derived from bone marrow and adipose tissue are the most feasible cell source for cartilage engineering.⁸² Chondrogenic differentiation can be achieved with growth factor induction⁸³ or co-culture with chondrocytes⁸⁴ or with chondrogenic matrices.⁸⁵ In recent years, mimicking native histoarchitecture and the molecular signaling of cartilage microenvironment in scaffold design have been considered important to facilitate stem cell chondrogenic differentiation and cartilage formation.⁸⁶ Therefore, optimization of chondrogenic induction regime by proper combination of paracrine factors, chondrogenic matrices, and suitable topographical structure of scaffold is likely to enhance chondrogenic differentiation of stem cells, and improve the structure and function of stem cell-engineered cartilage.

In vitro engineering of cartilage with enhanced mechanical strength

As described above, the application of plastic surgery requires immediately available cartilage graft to generate an auricular or a nasal frame for reconstructive surgical procedures. *In vivo* engineering cartilage, first using the human body as a bioreactor and then reshaping the *in vivo*-engineered cartilage block into a desired frame, would require at least two-stage operations.⁶⁸ Furthermore, patients may undergo unnecessary suffering if the first stage of *in vivo* engineering fails. Therefore, *in vitro* cartilage engineering can not only avoid two-stage operations, but also reduce the risk of failure because more back-up engineered cartilages can be made simultaneously *in vitro* without causing patient suffering.

Today, *in vitro* cartilage engineering has already been proven feasible by experimental studies using either chondrocytes⁶⁵ or mesenchymal stem cells.⁸⁷ Nevertheless, the mechanical strength of *in vitro*-engineered cartilage remains relatively weak compared to that of *in vivo*-engineered cartilage.⁸⁸ This is likely caused by the differences between *in vitro* and *in vivo* microenvironments, and the latter can promote the maturation of engineered cartilage and thus lead to differential expression of key matrix molecules such as collagen IX and pyridinoline, and enhanced mechanical strength.⁸⁸ Although it remains difficult to define the environmental mechanism, partially mimicking *in vivo* microenvironmental factors may help to enhance the mechanical property of *in vitro*-engineered cartilage. For example, when an articular cartilage was engineered in a bioreactor with dynamic loading, it was found that continuous dynamic loading could significantly increase Young's modulus of the engineered cartilage. In addition, the loaded cartilage increased the production of cartilage oligomeric matrix protein and collagens II and IX.⁸⁹ In the

future, mechanical loading as well as other factors that are able to facilitate collagen maturation may represent one of the future directions for *in vitro* cartilage engineering.

Design and precise control of engineered cartilage 3D structure

For engineered cartilage application in auricular and nasal reconstruction, precise control of 3D structure is necessary to

achieve the goal. As previously described, a CAD/CAM system is essential to collect the 3D information and to fabricate the scaffold with a specific 3D structure that matches a patient's own auricular or nasal structure. In addition, the fabrication of a suitable scaffold that is able to maintain the precise 3D structure during cartilage formation may be an important consideration. Furthermore, an inner core stent with slow degradation rate may help to maintain the 3D structure if the inner core starts to degrade after mature cartilage formation.

Repair and grafting of bone

Iris A. Seitz, Chad M. Teven, and Russell R. Reid

SYNOPSIS

- This chapter will concentrate on the principles and concepts of bone repair, grafting, and reconstruction.
- The embryology, physiology, microanatomy, and histochemistry of bone will be reviewed.
- Principles of mechanotransduction and cellular mechanisms of bone turnover will also be discussed.
- Pathophysiology of traumatic injury to bone (fractures, segmental loss, defects) will be categorized and reviewed.
- Bone-remodeling mechanisms (osteoconduction, osteoinduction, osseointegration) will be described.
- After a brief history of autogenous bone grafting, the clinical application of bone transfer and transplantation will be captured by a brief atlas of harvest of each subtype.
- The reader will also be provided with a brief overview of bone substitutes.

Microanatomy and histochemistry

Bone is a complex structure that serves many roles within the body. It is crucial for maintaining mineral homeostasis, provides protection to internal organs, and offers structural support for locomotion and stature. Osseous tissue undergoes continuous remodeling, during which old bone is degraded and replaced by new bone. Most organs in the adult human undergo repair with scar tissue after injury. Bone, however, regenerates, making it a unique organ system.

The formation of bone occurs by either intramembranous ossification or endochondral ossification. Direct condensations of mesenchymal stem cells (MSCs) initiate the process of intramembranous ossification to create flat bones of the craniofacial skeleton. During intramembranous ossification, osteoblasts lining skeletal surfaces deposit new bone upon previously laid bone in a process called *apposition*.

Alternatively, endochondral ossification is characterized by the formation of an MSC-derived hyaline cartilage template that is subsequently replaced by bone. Endochondral ossification is responsible for the development of tubular long bones of the appendicular skeleton as well as the bones of the vertebral column and pelvis.¹⁻⁴

Bony tissue contains osteocytes located within open cavities called *lacunae*. Osteocytes project radiating processes through microscopic canaliculi that adjoin neighboring lacunae. Osteocytic cytoplasmic processes are linked to one another via gap junctions,⁵ through which osteocytes communicate.⁶

Cortical versus cancellous bone

The skeleton is comprised of cortical and cancellous bone (Fig. 18.1). Cortical bone is compact and forms the outer skeleton. It accounts for 80% of osseous tissue. Cortical bone is dense and strong to support the body and protect organs. A bilayered cellular membrane (*periosteum*) covers cortical bone. The outer layer is composed of a dense fibrous membrane containing flat fibroblast-like cells and serves as an attachment for muscles and tendons. Large plump cells line the inner periosteal layer (*cambium layer*) and can differentiate into osteoblasts upon stimulation. Bone also contains a thin layer of vascular connective tissue (*endosteum*) that lines the medullary cavity.

The primary functional unit of cortical bone is the osteon or haversian system (Fig. 18.2). An osteon contains concentric layers of cortical tissue (lamellae) that surround a central haversian canal that contains vascular and nervous tissue. Nutrient vessels within haversian canals anastomose to blood vessels in bone marrow and periosteum via the perpendicular running Volkmann's canals.

Cancellous or trabecular bone comprises approximately 20% of the skeleton. Relative to cortical bone, cancellous bone is porous and is located deep within the medullary cavity, typically at the ends of long bones. It consists of bony trabeculae oriented along the lines of stress. Cancellous and cortical bone are chemically equivalent; however, cancellous bone has increased metabolic activity due to its greater surface area for

Fig. 18.1 Diagrammatic representation of axial compact cortical bone microarchitecture.

remodeling. Cancellous bone provides internal support for bone marrow elements and cortical bone.

The chemical composition of bone

Inorganic phase

Bone is a calcified tissue composed of 60% inorganic matter, 30% organic matter, and 10% water. The inorganic component of bone makes up approximately 40% of bony volume, while the organic component and water comprise 35% and 25%, respectively.^{7–10} The inorganic phase primarily consists of the mineral crystal hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$), which measures 20–25 nm in length, 15 nm in width, and 2–5 nm in thickness.⁷ It is the hydroxyl endmember of the apatite group; however, impurities arise when the hydroxyl group is replaced by potassium, magnesium, or sodium; or when carbonate replaces the phosphate group.^{7,10–14} By storing them as a mixture within impure hydroxyapatite, bone provides a reservoir of various minerals within the body.

Organic phase

The organic component of bone (demineralized organic bone matrix or osteoid) is deposited by osteoblasts during bone formation. Osteoid is primarily composed of type I collagen, but also includes many noncollagenous proteins.⁹ Collagen is a trilaminar protein consisting of two $\alpha 1$ chains and one $\alpha 2$ chain that form a distinct right-handed helical structure. Within the rough endoplasmic reticulum of osteoblasts, procollagen undergoes hydroxylation and glycosylation before

transfer to the Golgi apparatus, where it is packaged and secreted. Extracellularly, procollagen peptides are cleaved into tropocollagen. The copper-dependent enzyme lysyl oxidase mediates covalent cross-linking within and between tropocollagen molecules to create mature collagen fibers. The strength of bone is derived from interactions between collagen fibers and inorganic minerals.

The cellular composition of bone

Three cell types are predominantly found in bone: osteoblasts, osteocytes, and osteoclasts (Table 18.1).

Osteoblasts

Histology and function

Osteoblasts are derived from MSCs that have the capacity to differentiate into several connective tissue cell types.¹⁵ Within the appropriate osteogenic environment, MSCs differentiate into osteoprogenitor cells, thereby committing to an osteoblastic lineage. Osteoprogenitor cells are ubiquitous in bone, located within Volkman's and haversian canals, the cambium layer of periosteum, endosteum, and within perivascular tissue adjacent to bone.¹⁶

Fig. 18.2 (A) Cross-section of compact bone as seen by microradiography. Note that the osteons are oriented in the longitudinal axis of long bone. The dark masses represent recent decalcified osteons. The light masses represent older calcified osteons. (B) A single osteon of the haversian system.

Table 18.1 Bone cells

Cell type	Morphology	Location	Function	Source	Precursor cell	Differentiation product
Osteoblast	Rounded, basophilic cells Stain strongly for alkaline phosphatase	External surfaces of bone in areas of active remodeling and bone formation Bone surfaces in fractures	Produce bone matrix	Periosteum Endosteum Bone marrow ? Others	Preosteoblast ? Bone-lining cells	Osteocyte
Osteocyte	Stellate cells with thin cytoplasmic processes	Embedded in lacunae	Exact function unknown Potential functions: Mechanosensory Mineral homeostasis Bone resorption	Osteoblasts that become embedded in osteoid	Osteoblasts	Terminally differentiated cell
Osteoclast	Large, multinuclear cells with ruffled border Stain positive for tartrate-resistant acid phosphatase	Endosteal and periosteal surfaces of bone in areas of active remodeling On fractured bone surfaces	Bone resorption	Bone marrow Spleen ? Lung, peritoneum, peripheral blood	Hematopoietic stem cell	None

Osteoblasts are plump, basophilic cells located on the external surfaces of bone at areas of active bone formation during development and fracture repair. They have a vast endoplasmic reticulum for robust collagen production and contain many mitochondria and a large Golgi apparatus to package and secrete procollagen. Osteoblasts are responsible for the production of bony matrix and facilitate the mineralization of osteoid.^{16–18} Some osteoblasts will eventually become surrounded with bony matrix and terminally differentiate into osteocytes.

During osteoprogenitor cell differentiation, cells halt proliferation and start expressing proteins characteristic of an osteoblastic lineage. Preosteoblasts secrete proteins (e.g., alkaline phosphatase (ALP)) that denote early osteogenesis,^{4,19,20} and also begin to produce bony matrix proteins. As the differentiation process ensues, cells display a basophilic appearance, stain strongly for ALP, and lose the ability to proliferate. Mature osteoblasts deposit significant osteoid. They also play a role in many other processes as indicated by their secretion of numerous cytokines and noncollagenous proteins that have pleiotropic effects, as well as factors important for myelopoiesis.^{16,21} Differentiated osteoblasts affect bone metabolism and mineral homeostasis by interacting via surface receptors with parathyroid hormone and 1,25-dihydroxyvitamin D. Most osteoblasts ultimately undergo apoptosis or become bone-lining cells. However, 20% differentiate into osteocytes.²²

Regulation of osteoblast differentiation

Major signaling pathways

Under the control of multiple signaling pathways, preosteoblasts differentiate into mature osteoblasts. The Wnt pathway,^{23–26} the TGF- β /BMP superfamily,^{19,27–29} notch signaling,^{30–32} hedgehog proteins,^{33–36} and fibroblast growth factors^{37–40} (FGFs) have all been implicated in the molecular

signaling of osteogenesis. Although the exact mechanisms of osteogenesis are complex and only partially elucidated, advances have been made regarding the initiation and molecular control of this process. Wnt/ β -catenin signaling has been shown to control the differentiation of both osteoblasts and osteoclasts, which may be important in postnatal bone acquisition.⁴¹ Wnt/ β -catenin signaling is also important during skeletogenesis in the fetus, and is considered to be partially responsible for both osteoblast and chondrocyte differentiation.^{42,43} Notch signaling is a highly conserved signaling system involving cell–cell communication. In addition to cell fate division and homeostatic maintenance, the notch pathway is believed to be important in osteogenesis because of notch1–BMP-2 interactions that promote osteogenic differentiation.⁴⁴ Additionally, Engin *et al.*⁴⁵ showed with osteoblast-specific gain of Notch function studies that Notch not only stimulates terminal osteoblast differentiation, but that it also plays a role in the proliferation of immature osteoblasts. In addition, loss of notch signaling is associated with the expression of an osteoporotic phenotype.⁴⁵

Hedgehog signaling plays a role in many embryonic processes and also is involved with the maintenance of stem cells in adults. There are three mammalian Hedgehog orthologs: Desert, Sonic, and Indian. Sonic Hedgehog and Indian Hedgehog both have important roles in osteogenesis.^{33,34,46–49} Specifically, Indian Hedgehog is critical for endochondral bone formation,⁵⁰ whereas Sonic Hedgehog appears to be important for skeletal patterning.⁵¹

Transcriptional regulation

Many transcription factors play a significant role in osteogenesis. Runt-related transcription factor 2/core-binding factor alpha 1 (RUNX2/CBF α -1) and Osterix have important effects on osteoblast differentiation.^{52–57} RUNX2 is the mammalian homolog of the *Drosophila* transcription factor Runt and is

believed to be evolutionarily conserved in humans to serve a critical role throughout the many steps of osteoblastogenesis, including osteoblast induction, proliferation, and maturation. Homozygous deletions of the Runx2 gene are uniformly lethal in mice due to a complete lack of mineralized bone matrix.⁵³ Runx2 haploinsufficiency causes cleidocranial dysplasia, an autosomal-dominant disease in humans characterized by hypoplastic clavicles, dental deformities, shortened stature, brachycephaly, hypertelorism, and other skeletal defects.⁵⁸ While the exact mechanisms that control the regulation of Runx2 have not been fully decoded, studies have shown that various histone acetyltransferases are important Runx2 cofactors.^{59,60} Additionally, microRNAs appear to regulate Runx2 protein expression.⁶¹ MicroRNAs play critical roles in stem cell function,^{62,63} and thus may have important clinical implications for diseases due to dysfunctional MSC/Runx2 interactions. Many other regulators also play an important role in Runx2 function^{64–70}; however, their exact roles are currently under study.

The zinc finger-containing protein osterix (Osx) is also a key transcription factor to bone formation.^{55,71} Osx-null mice form neither cortical nor cancellous bone. Unlike Runx2-null mice, however, Osx-null mice still produce normal cartilage.⁷² As a result of the findings that Osx expression is absent in Runx2 knockout mice, whereas Runx2 expression is normal in Osx-null mice, the Osx gene is thought to be downstream to Runx2.⁵⁵ Nishio *et al.*⁷³ confirmed this using overexpression experiments to show that Runx2 transactivates the Osx gene promoter significantly, indicating that there is a Runx2-binding element within the promoter region.

The signaling pathways and transcription factors responsible for osteoblastogenesis are exquisitely detailed elsewhere.^{74,75}

Osteocytes

Histology

Osteocytes are terminally differentiated cells of the osteoblast lineage and comprise 90–95% of all bone cells. Despite being the most abundant cell in bone, osteocytes are the least well characterized. Osteocytes are located within lacunae. Multiple cytoplasmic processes radiate from osteocyte somas and travel through canaliculi between lacunae. Gap junction connections between adjacent cytoplasmic processes enable osteocytes to communicate with one another. Osteocytes communicate with osteoblasts by way of this canalicular network as well. Processes also extend to the haversian canals so that osteocytes can rid themselves of waste products and receive nutrients necessary for survival. Relative to osteoblasts, osteocytes have qualitatively similar organelles, but the organelles are smaller in both size and number.⁷⁶

Osteocyte function

Bone is a dynamic substance that maintains its viability by constantly adapting to the environment in which it lives. Victim to mechanical loading and various traumas, bone must have a way to recognize such stressors. It is believed that osteocytes are mechanosensory cells that translate (via mechanotransduction) physical stress into chemical and/or electrical signals that stimulate bone remodeling.^{77–79} This hypothesis has been derived from various lines of evidence. Anatomically, osteocytes form a syncytium with surrounding cells via their cellular processes. These connections may provide

communication between mechanical stimuli and effector cells (osteoblasts and osteoclasts). Recent evidence has shown that osteocyte processes also attach to ECM proteins and may mediate mechanotransduction by the amplification of shear stress experienced at the ECM.⁸⁰ In addition, mechanical loading alters osteocyte gene expression. Osteocytes rapidly produce increased levels of *c-fos*, IGF-1, prostaglandin (PG), and nitrous oxide (NO) when mechanically stimulated.^{81–83} These and many other molecules (see below) have numerous effects on bone turnover. Molecular studies have implicated the activation of the Wnt/ β -catenin pathway in response to loading.^{84,85} The osteocytic Wnt/ β -catenin pathway appears to be triggered by crosstalk with various signaling pathways when the osteocyte senses a load strain, thereby decreasing negative regulators of the Wnt/ β -catenin pathway,⁸² an important regulator of bone mass. Finally, Tatsumi *et al.*⁸⁶ have shown that targeted ablation of osteocytes induces osteoporosis with defective mechanotransduction.

One potential function of the osteocyte, termed periosteocytic osteolysis, has remained elusive. Osteocytes may fulfill an osteoclast-like activity by resorbing varying amounts of calcified bone matrix surrounding their lacunae. Evidence for this comes from studies that have shown a larger than expected size of lacunae in conditions characterized by increased bone resorption.^{87–89} Additionally, the administration of parathyroid and thyroid hormone has been shown to induce microradiographic enlargement of lacunae, thought to be the result of the hormones' actions on osteocytes.^{90,91} Recently, Wysolmerski⁹² suggested that osteocytes have a role in coordinating bone and mineral metabolism during reproductive cycles. Specifically, osteocytes reversibly remodel perilacunar and pericanalicular bone during lactation by removing mineralized tissue in order to liberate calcium (and potentially phosphorous) for milk production. This tissue is then replaced during the recovery period after weaning.

Osteoclasts

Histology and function

Osteoclasts are multinucleated cells primarily responsible for bone resorption, a process necessary for bone growth, tooth eruption, fracture repair, and calcium homeostasis. Osteoclasts typically have between three and 25 nuclei per cell and are approximately 40 μ m in diameter. Histologically, osteoclast cytoplasm has a characteristic homogeneous, “foamy” appearance due to a high concentration of vesicles and vacuoles. Osteoclasts are derived from hematopoietic progenitor cells and are related to the monocyte/macrophage lineage. Osteoclasts are found on the endosteal and periosteal surfaces of bone in areas of active remodeling.

Bone resorption is a complex process by which crystalline hydroxyapatite is dissolved and organic bone matrix is degraded. *In vitro* bone resorption models using primary osteoclast isolates provided the basis for the resorption cycle.^{93,94} The cycle is a complex series of actions which includes osteoclast migration to the resorption site and attachment to bone, membrane polarization, dissolution of hydroxyapatite followed by degradation of organic bone matrix, removal of degradation products, and osteoclast inactivation or apoptosis.⁹⁵ Clinically, bone resorption is an extremely important process, as evidenced by pathologic conditions characterized by dysfunctional resorption. For example, increased osteoclastic function

leads to excess bone resorption, thereby causing osteoporosis. In contrast, osteoclast underactivity decreases bone resorption, which causes osteopetrosis.

Bone resorption is key for both bone remodeling at sites of injury and also as a mechanism of calcium homeostasis. Osteoclasts are stimulated to resorb bone by growth factors and cytokines secreted by local osteoblasts.⁹⁶ Once osteoclasts localize to the area in need of resorption they form a tight seal that separates the area of bone to be resorbed from the extracellular environment. Evidence has pointed to integrins (in particular integrin $\alpha_v\beta_3$) and cadherins as playing a prominent role in the attachment of this sealing zone.^{97–99} Myosin and actin-binding proteins are also important for such attachments.^{100,101} After sealing zone attachments are completed, osteocytes polarize such that the area adjacent to the resorbing bone surface becomes ruffled. The ruffled border is a specialized membrane domain formed by the fusion of intracellular acidic vesicles and functions as the osteocyte's resorbing organelle.^{102,103} Finger-like projections from the ruffled border increase the effective surface area of resorption. Before proteolytic cleavage of the organic matrix occurs, osteoclasts dissolve hydroxyapatite crystals by targeted secretion of hydrochloric acid through the ruffled border toward the resorption pit (Howship's lacuna).⁹⁵ After the dissolution of inorganic matter, many proteolytic enzymes, including matrix metalloproteinase-9 and cathepsin K, are secreted into the resorption lacuna to degrade the organic components of bones.^{104,105} Both phases of bone are subsequently removed from the resorption lacuna via transcytosis through the ruffled border and sent to the secretory domain of the osteoclast, which then expels these degradation products into the extracellular space outside the osteoclast.^{106–108} The osteocytic marker tartrate-resistant acid protease (TRAP) has been localized to transcytotic vesicles of resorbing osteoclasts, and is believed to generate reactive oxygen species that degrade matrix degradation products within these vesicles.¹⁰⁹

Osteoclast differentiation

The mechanisms surrounding osteoclast differentiation are complex and have been the subject of intense study. Depending on local stimuli, hematopoietic stem cells may differentiate into osteoclasts, macrophages, or dendritic cells. Macrophage colony-stimulating factor (M-CSF) and receptor activator for nuclear factor κ B (RANK) and RANK ligand (RANKL) are early mediators that signal osteoclastogenesis.^{110–115} In murine studies, M-CSF is functionally lacking in *op/op* mice, which express an osteopetrotic phenotype.^{116,117} In addition, in order for osteoclastogenesis to commence, RANKL (found on the cellular membrane of osteoblasts) must interact with RANK, a receptor found on osteoclast precursors.^{118–120} RANK–RANKL interaction must occur in order for osteoclast precursor cells to begin expressing phenotypic markers (e.g., TRAP) that characterize osteoclasts. Similar to *op/op* mice with functionally absent M-CSF, RANK and RANKL knockout mice also express an osteopetrotic phenotype.^{113,115,121}

Osteoprotegerin (OPG), a TNF-related soluble protein secreted by osteoblasts, is also an important regulator of osteoclastogenesis. OPG has effects on bone density and bone mass^{118,122} by acting as a decoy receptor for RANK, thereby blocking RANK–RANKL interaction. Transgenic mice that overexpress OPG suffer from an osteopetrotic

phenotype¹²², while OPG knockout mice display an osteopetrotic phenotype.^{123,124}

The RANK molecule lacks enzymatic activity, and thus must recruit adaptor proteins when stimulated by RANKL to promote differentiation.^{125–127} TNF receptor-associated factor (TRAF) family members appear to be important adaptor proteins, with TRAF6 serving the most critical role.^{128–130} TRAF6 knockout mice develop severe osteopetrosis as a result of either the dysfunction or total absence of osteoclasts.^{131,132} Moreover, TRAF6 activates NF- κ B, another essential modulator of osteoclast differentiation.^{133,134} NF- κ B enters the nucleus of osteoclasts stimulated with RANKL, and regulates transcription of target genes critical for osteoclastogenesis.¹³⁵

Extracellular matrix

The extracellular matrix (ECM) is the scaffolding from which bone derives much of its strength and architecture. Most molecules found within the ECM are produced by osteoblasts. The ECM contains nearly 30 types of collagen, as well as noncollagenous phospho- and glycoproteins. Type I collagen is the predominant form found within the ECM, making up approximately 90% of bone matrix. The significance of type I collagen is highlighted by patients with osteogenesis imperfecta (OI), a disease characterized by bone fragility and repeated fracture. OI often occurs in patients with pro- α 1 or pro- α 2-chain gene mutations, or from a mutation in one of the enzymes responsible for posttranslational hydroxylation of collagen.¹³⁶ In addition, bone mineralization takes place within the ECM. Bone mineralization is a well-orchestrated process during which hydroxyapatite crystals are laid down within the organic matrix of bone and calcify proteins that are secreted by osteoblasts.

In addition to type I collagen, many noncollagenous proteins are found within the ECM (Table 18.2). Osteopontin is a ubiquitous phosphoprotein that exists in multiple forms. It has been localized to most cells within bone, including osteoblasts, osteocytes, osteoclasts, and bone precursor cells.^{137–139} Osteopontin plays a role in the nucleation of hydroxyapatite crystals during matrix mineralization and also in osteoclast adhesion during bone remodeling.^{140–145}

Osteonectin is a glycoprotein that binds to calcium and type I collagen and also initiates and regulates bone mineralization.^{146,147} BSP is another important noncollagenous protein that, in contrast to osteopontin and osteonectin (both of which are expressed by many tissues throughout the body), is mainly expressed by cells within the skeleton.¹⁴⁸ BSP is an acidic phosphoprotein that binds to collagen and also promotes hydroxyapatite nucleation.¹⁴⁹ BSP-null mice express a phenotype characterized by small and undermineralized bones.¹⁵⁰

Osteocalcin (bone Gla protein) is a vitamin K-dependent γ -carboxyglutamic acid-containing protein, similar to factors II, VII, IX, and X of the coagulation cascade. The most abundant noncollagenous protein in bone, osteocalcin is secreted by osteoblasts and odontoblasts and is an important marker of increased bone turnover.¹⁵¹ Osteocalcin plays a role in bone turnover,^{152,153} osteoclast differentiation,¹⁵⁴ and energy metabolism.^{155,156}

Osteoblasts also produce proteoglycans, the most abundant of which is biglycan (BGN). BGN, a leucine-rich noncollagenous protein, is believed to play a role in the mineralization of bone given that *bgn*-deficient mice express an osteopetrotic phenotype.¹⁵⁷ However, BGN seems to play an important role

Table 18.2 Extracellular matrix molecules in bone

Molecule	Protein structure	Cell source	Present in nonosseous tissues	Function	Phenotype of knockout animals or deficiency in humans
Collagen type I	Trilaminar protein consisting of 2 α 1 chains and 1 α 2 chain	Many Mature and immature osteoblasts in bone	Yes	Primary scaffold of bone 90% of matrix	Osteogenesis imperfecta in humans
Alkaline phosphatase	Metalloenzyme	Mature and immature osteoblasts Different isoforms expressed by cardiac and hepatic cells	Yes	Enzyme Regulator of extracellular matrix mineralization Regulator of cellular migration, adhesion, and differentiation	Hypophosphatemia and defects in skeletal mineralization in knockout mice
Osteopontin	Phosphorylated glycoprotein	Osteoblasts/ osteoclasts Tumor cells (e.g., breast)	Yes	Osteoclast activation and extracellular matrix mineralization Anchor osteoclasts to mineralized matrix	Alterations in extracellular matrix remodeling in knockout mice
Osteonectin	Glycoprotein	Osteoblasts Endothelial cells, megakaryocytes	Yes	Binds calcium and collagen type I Regulator of mineralization	Unknown
Bone sialoprotein	Phosphorylated glycoprotein	Almost exclusively produced by skeletal cells (osteoblasts, osteocytes, hypertrophic chondrocytes)	No	Exact function unknown Regulator of cellular adhesion	Unknown
Osteocalcin	Vitamin K-dependent γ -carboxyglutamic acid-containing protein	Osteoblasts Odontoblasts Hypertrophic chondrocytes	No	Regulator of bone turnover Regulator of osteoclast migration Binds hydroxyapatite	Osteopetrosis in knockout mice
Biglycan	Proteoglycan	Mature and immature osteoblasts Nonosseous cells	Yes	Exact function unknown Regulates function apatite formation	Osteoporosis and small, thin, short limbs in knockout mice

outside the skeleton as well, as *bgn*-knockout mice manifest spontaneous aortic rupture and dissection,¹⁵⁸ dental and muscular abnormalities, thinning of skin, and osteoarthritis.¹⁵⁹

A variety of enzymes produced by bone cells also function within the ECM. The most prominent is ALP. Like osteocalcin, ALP is often used as a marker of bone turnover.¹⁶⁰ While the exact function of ALP is unknown, it is believed to be important for bone mineralization, during which it regulates apatite formation.

Principles of bone homeostasis and turnover

Unique to bone is its ability to undergo regeneration rather than repair with scar formation, as is typified by most

other tissues within the body. As described previously, bone is subject to constant remodeling, a process mediated by osteoclasts and osteoblasts. Physiologically, bone homeostasis is maintained by the counterbalancing of bone resorption with formation. When one of these processes becomes dysfunctional, patients may manifest a distinct pathology. Excessive bone resorption resulting in an excessive loss of bone is the fundamental pathogenesis underlying osteoporosis.¹⁶¹ Conversely, decreased bone resorption due to decreased osteoclast activity leads to an osteopetrotic phenotype.¹⁶² Decreased bone resorption due to increased osteoblast activity, however, will produce an osteosclerotic phenotype.

The structure of bone is a function of its material composition as well as the genetic blueprint of an individual. In addition, various loads to which bone is subjected define its

structure. This process of functional adaptation mediates repair of damaged bone and also facilitates prevention of damage before it may occur. Bone exhibiting suppressed remodeling and resorption suffers increased microdamage and fracture accumulation.^{163,164} It has been demonstrated that sites of microcracks are subsequently associated with new bone remodeling more often than expected by chance,^{165–167} which has led to the belief that bone remodeling and repair are often targeted to specific locations.¹⁶⁸

Wolff's law and mechanotransduction

Wolff (1892) derived a mathematical formula to describe how changes in the form and function of bone could lead to a change in its internal architecture and external structure.¹⁶⁹ Wolff believed that during the functional adaptation of bone to new loads that occur during one's life (e.g., as a result of trauma), the trabeculae within bone would reorient to align with the new principal stress trajectories of these environmental loads. Wolff's contributions were key to the early understanding of bone adaptation. More recently, authors have recognized that bones are subject to dynamic applied loads.¹⁷⁰

Considerable research has examined the initial events that stimulate bone adaptation. It is believed that the stimulus for bone remodeling is strain (the physical deformation of bone tissue).¹⁷¹ Osteocytes, the mediators of mechanotransduction,¹⁷² respond molecularly to mechanical loads. They undergo direct deformation by bending and also are deformed by the electrical potential induced by the flow of surrounding interstitial fluid.^{173,174} In addition, osteocytes are subjected to shear stress by the physical flow of interstitial fluid around their cellular membranes.^{175–179}

When strained, osteocytes convert the mechanical stimulus into chemical or electrical activity in a process thought to require various signaling molecules including NO and PGs.¹⁷² Interestingly, NO synthase, a calcium/calmodulin-dependent enzyme, is activated under conditions of increased intracellular calcium; intracellular calcium concentrations appear to increase in response to fluid flow.^{180,181} Klein-Nulend and colleagues¹⁸² demonstrated that a pulsating fluid flow model led to the release of NO from osteocytes. Taken together, these studies indicate that NO may be important in osteocyte mechanotransduction.¹⁸³ Additional studies have shown that pulsating fluid flow treatment also stimulates osteocytes to synthesize increased levels of PGE₂ and PGI₂,^{184,185} as well as increased levels of cyclooxygenase-2 (COX-2) mRNA.¹⁸⁶ COX-2 production is also stimulated by mechanical loading.^{187,188} Thus, COX-2 induction and the production of PGs are thought to be important mediators in the conversion of mechanical shear forces into signals that trigger bone turnover.

Bone regeneration: the role of the stem cell

In the last decade, the field of regenerative medicine has exploded with the discovery of new techniques to isolate cells capable of differentiating into many different tissues. In particular, the MSC (Fig. 18.3) has considerable therapeutic potential for fracture repair and other bone pathologies. For concordance, Dominici and colleagues¹⁸⁹ have proposed that MSCs meet the following criteria: (1) isolated MSCs must

Fig. 18.3 Schematic representation of mesenchymal stem cell (MSC) differentiation pathways. MSCs are pluripotent stem cells that are capable of differentiating into several lineages with distinct growth and differentiation cues. These lineages include osteogenic, chondrogenic, adipogenic, and myogenic lineages. Lineage-specific differentiation is a well-coordinated process that is regulated by master regulators, such as MyoD for myogenesis, peroxisome proliferator-accepted receptor (PPAR)- γ for adipogenesis, SOX9 for chondrogenesis, and RUNX2 and Osterix for osteogenesis. Osteogenic differentiation can be staged by measuring alkaline phosphatase (early marker) and osteopontin and osteonectin (late markers). (From Tang N, Song W-X, Luo J, et al. Osteosarcoma development and stem cell differentiation. Clin Orthop Relat Res. 2008;466:2114–2130.)

adhere to plastic in culture; (2) MSCs should express the CD105, CD73, and CD90 surface antigens and not express the CD34, CD45, CD14 or CD11B, CD79A or CD19 and human leukocyte antigen-DR (HLA-DR) surface antigens; and (3) MSCs must have the capacity to differentiate into osteoblasts, adipocytes, and chondroblasts. MSCs and MSC-like cells are derived from bone marrow, but can also be expanded from skeletal muscle,¹⁹⁰ adipose tissue,¹⁹¹ dental pulp,¹⁹² the circulatory system,¹⁹³ synovium,¹⁹⁴ amniotic fluid,¹⁹⁵ urine,¹⁹⁶ the umbilical cord,¹⁹⁷ and fetal tissues.^{198,199}

The capability of MSCs to differentiate into and assist with the restoration and repair of bone has been extensively studied.^{200–203} MSCs are also used clinically in patients with various bone disorders.²⁰⁴ In a clinical trial²⁰⁴ that examined MSC administration to children with OI, bone mineral density, growth velocity, and ambulation all improved after MSC administration. However, the concentration of MSCs detected in bone, skin, and other tissues was less than 1%. These data and evidence from additional studies^{205,206} have led authors to postulate that MSCs may actually secrete soluble factors that alter tissue microenvironment, which may be an important mechanism by which MSCs repair tissue.^{207,208}

Molecular mechanisms of bone regeneration

Bone regeneration consists of a complex interplay of molecular processes that promote MSC migration, proliferation, and differentiation. Recently, there has been a great deal of research aimed at the identification of these molecular processes, and advances in our understanding of the molecular mechanisms of bone regeneration have been made. Many have been able to identify important signaling molecules as well as transcriptional regulators of bone regeneration (Table 18.3).

Bone morphogenetic protein

In the 1960s, Urist²⁰⁹ discovered the function of BMP from his work with demineralized bone matrix (DBM). To date, approximately 20 BMP isoforms have been characterized. BMPs are pleiotropic members of the TGF- β superfamily. BMPs, while important for brain and bone formation *in utero*,^{210–212} have generated much of their recognition from their osteoinductive properties. BMPs have also been implicated in human disease.²¹³

BMPs are synthesized as large precursor molecules that consist of characteristic subsections. A series of seven cysteine residues is located at the carboxyl termini of BMPs, and is important for proper protein folding. BMPs also contain a

signal peptide, a prodomain, and a mature peptide.²¹⁴ BMPs are thought to be secreted from cells in their active form.

BMPs are natural ligands for type I and type II serine/threonine kinase transmembrane cellular surface receptors. There are three type I and three type II receptors that are capable of binding BMPs.²¹² Upon ligand (BMP) binding, a heterotetrameric complex is formed, after which type II receptor kinase domains phosphorylate Gly-Ser domains in the type I receptor kinases. This process activates type I receptors to recruit and phosphorylate intracytoplasmic SMAD proteins (SMADs 1, 5, and 8). Following SMAD phosphorylation, SMAD 1, 5, or 8 will bind to SMAD 4, and this SMAD4-phosphorylated SMAD 1, 5, or 8 complex will relocate to the cell nucleus. Transcription factor activation occurs, leading to the transcription of bone morphogenetic target genes.^{215,216}

Bone morphogenetic protein function

BMP exerts pleiotropic effects throughout the lifespan of an organism. In the early stages of human development, BMP plays a key role in skeletogenesis.²¹¹ Also during this time period, BMP signals epidermal induction,²¹⁷ directs the development of neural crest cells,²¹⁸ and induces a sympathetic adrenergic phenotype.²¹⁹ Bmp-2-null mice typically die between 7 and 10 days of gestation due to cardiac defects, even before the formation of bone begins.

Table 18.3 Growth factors and fracture repair

Molecule	Ectopic bone formation	Segmental defect healing	Effect on fractures	Combination with other growth factors	Effective in lower vertebrates	Effective in primates	Potential clinical use
BMPs	Yes	Endochondral ++++ Membranous ++++	Increase callus volume Increase mechanical strength ? Increase rate of healing	Synergistic with TGF- β	Yes	Yes	Spinal fusion Alveolar bone deficiency Segmental defects Augment bone graft healing Dental implants
TGF- β	No	Endochondral ++ Membranous ++	Increases callus size Increases mechanical strength	Synergistic with BMP Increases FGF-2 expression Increases VEGF expression	Yes	No (limited study)	Role alone unclear
FGFs	No	Endochondral +/- Membranous +/-	Increase callus and bone volume Increase mechanical strength	Increase VEGF expression ? Synergistic with TGF- β	Yes	Yes (limited study)	Potential for augmenting angiogenesis in compromised wounds
PDGF	No	Endochondral - Membranous -	Increases callus volume Increases mechanical strength	Increases VEGF expression Synergistic with TGF- β for chemotaxis	Yes	No	Unknown

++++, very active; +/-, minimally active; -, no activity. BMPs, bone morphogenetic proteins; TGF- β , transforming growth factor beta; FGFs, fibroblast growth factors; PDGF, platelet-derived growth factor; VEGF, vascular endothelial growth factor.

BMP is the only signaling molecule capable of singly inducing *de novo* bone formation. It has been hypothesized that BMP-2, -6, and -9, and to a lesser extent, -4, and -7, various BMP isoforms, have the greatest osteogenic capacity.²²⁰ Luu and colleagues¹⁹ infected HEK293, C2C12, and C3H10T1/2 cells with adenoviral vectors containing various BMP isoforms (AdBMP). The authors measured the expression of early (ALP) and late (osteocalcin) osteogenic markers *in vitro*. They also assessed *in vivo* induction of heterotopic ossification by implanting AdBMPs into nude mice and evaluating radiographic and histologic results at 3 and 5 weeks. BMP-2, -4, -6, and -7 were shown to induce increased ALP elevation compared to other BMPs. In addition, BMP-2, -4, -6, -7, and -9 stimulated increased osteocalcin expression compared to others. The authors also found that BMP-2, -6, -7, and -9 induced the greatest degree of osteogenesis *in vivo*. The authors concluded that BMP-2, -6, and -9 have the greatest osteogenic potential, and that BMP-4, and -7 also have a significant degree of osteogenic potential.

BMP-2 promotes osteoblast differentiation by stimulating Runx2 in a process mediated by Smad proteins.²²¹ In addition, BMP-2 affects osteoblast differentiation via activation of the β -catenin signaling pathway.²²² Interestingly, endogenous activation of β -catenin induces ALP mRNA expression; however, BMP-2 must be present for β -catenin signaling to induce osteocalcin expression as well.²²³ Thus, β -catenin-dependent differentiation processes likely require BMP-2 to promote the later stages of osteoblast differentiation. Recently, it has been demonstrated that BMP-2-mediated osteoblast differentiation is also dependent upon Akt2 selective signaling.²²⁴ IGFs are important for osteoblast differentiation and normal bone growth,^{225–228} and Akt2 is a key molecule within the insulin signaling pathway. Mukherjee *et al.*²²⁴ showed that, although BMP-2 signaling is normal, osteoblast differentiation does not occur in Akt2-knockout mice. Delivery of Runx2 to Akt2-deficient mice restores osteoblast differentiation; thus, Akt likely serves a specific role in osteoblast differentiation through its regulation of Runx2 gene expression.

Furthermore, BMP-2 appears to improve healing of large osseous defects. Many studies have evaluated recombinant human BMP-2 (rhBMP-2) in *in vivo* animal models. In nonhuman primate and other mammalian models, rhBMP-2 has been shown to augment bone growth successfully and also close critical-sized osseous defects.^{229–231} The efficacy of rhBMP-2 in humans has also been assessed.^{232,233} Slosar *et al.*²³⁴ demonstrated that anterior lumbar allografts filled with rhBMP-2 experienced higher fusion rates than lumbar allografts without rhBMP-2 in patients who underwent lumbar fusion. The authors demonstrated that at 6 months and at 2 years, allografts with rhBMP-2 shortened the time-frame for expected improvement, and also improved patients' Oswestry Disability Index scores. Thus, it has been concluded allografts with rhBMP-2 can offer reliable and clinically significant benefits.

Adenoviral delivery of BMP (AdBMP) is also effective in stimulating osteogenic differentiation of mesenchymal progenitor cells. Our group isolated and subsequently reversibly immortalized primary murine calvarial cells that retained a progenitor cell phenotype.²³⁵ Immortalized calvarial cells (iCALs) treated with AdBMP-2 demonstrated an increase in early (e.g., alkaline phosphatase activity, osteocalcin mRNA transcription) and late (e.g., matrix mineralization) marker

expression of osteogenic differentiation compared to iCALs treated with AdGFP (control). Additionally, *in vivo* stem cell implantation assays revealed increased ectopic bone production from iCALs exposed to BMP-2 compared to control. In a similar study that evaluated the capacity of BMP-9 to induce osteogenic differentiation of calvarial progenitor cells, Teven and colleagues²³⁶ demonstrated that AdBMP-9-treated iCALs display enhanced osteogenic differentiation compared to AdGFP-treated cells (control) in both the *in vitro* and *in vivo* settings. The translational utility of these experiments relates to identifying effective agents for bony (e.g., calvarial) tissue regeneration. However, the clinical use of adenovirally-delivered BMPs has been limited and therefore further investigation is warranted.

Presently, rhBMP-2 (INFUSE, Medtronic, Inc.) is one of two rhBMPs approved by the Food and Drug Administration (FDA) for human application. The other is rhBMP-7 (rhOP-1). As described, rhBMP-2 is often used in spinal fusion, as well as orthopedic trauma and dental procedures. rhBMP-7 has shown clinical benefits in spinal fusion and tibia repair.^{237,238} Interestingly, although BMP-2 may be more osteoinductive than BMP-7 based on *in vitro* analyses,²⁹ there has been relatively little *in vivo* data comparing the two. Barr and colleagues²³⁹ have found that rhBMP-7 promotes similar bone quality but greater bone volume induction than rhBMP-2 in murine muscle pouch assays analyzed by microscopic computed tomography and histology. However, other studies have found different results.²⁴⁰ Conflicting results may be due to differences in experimental design.

Transforming growth factor- β

TGF- β has protean effects on cellular processes within the human body. TGF- β has been implicated in cell cycle regulation, angiogenesis, wound healing, and skeletogenesis. TGF- β also appears to have significant roles in human disease.²⁴¹ There are three distinct human TGF- β isoforms (TGF- β 1, - β 2, and - β 3). Though they exhibit differences, each isoform shares similar functions with one another, including functions pertaining to the regulation of osteogenesis and osseous repair.

TGF- β , like BMP, contains a cluster of conserved cysteine residues.²⁴² Each isoform is produced as a precursor molecule consisting of TGF- β and a propeptide region. In contrast to BMPs, however, TGF- β is secreted as an inactive molecule and stored in its latent form within the ECM. TGF- β becomes active after the noncovalent disulfide bond linking TGF- β and its propeptide region is broken.

There are four TGF- β receptors identified: types I, II, and III, and endoglin. TGF- β -initiated signaling, like BMP-mediated signaling, uses SMAD protein intermediates. Active TGF- β binds to either type III or type II receptors, both of which promote the phosphorylation of type I receptors. Phosphorylation of SMAD2 or SMAD3 follows, which in turn leads to the binding of SMAD4 to the phosphorylated SMAD2 or SMAD3 proteins. This complex translocates to the cellular nucleus, where transcription factors activate specific target gene transcription, thereby mediating the effects of TGF- β at the cellular level.

Evidence that TGF- β may play a role in osteogenesis has come from experiments demonstrating that TGF- β is produced by osteoblasts²⁴³ and stimulates the production of

collagen and osteopontin.^{244,245} *In vivo* studies have corroborated the osteoinductive effect of TGF- β .²⁴⁶ TGF- β 1, in particular, has been the subject of a considerable body of literature with respect to its osteogenic potential, in part because it is the dominant TGF- β isoform expressed by bone cells.²⁴⁷ *In vitro* analyses have demonstrated that TGF- β 1, by recruiting and stimulating the proliferation of osteoblast progenitors, increases bone formation.²⁴⁸ Interestingly, TGF- β 1 seems to have a differential effect on osteoblast differentiation. Early phases of differentiation appear to be promoted by TGF- β 1, while later phases are blocked.²⁴⁹

In addition, TGF- β 1 modulates the processes of osteoclastogenesis and bone resorption. At high TGF- β 1 concentrations (0.1–10 ng/mL), osteoclastogenesis appears to be downregulated.²⁴⁸ TGF- β 1 binds to its receptor on osteoblasts and augments the expression of OPG while also decreasing RANKL expression. A lower RANKL:OPG ratio results in maximal RANKL occupation by OPG, thus decreasing maturation of osteoclasts. TGF- β 1 appears to serve a bifunctional role, however, as low concentrations are associated with high levels of both RANKL and RANK, and subsequent osteoclastogenesis.

TGF- β 1 may also be important for the coupling of bone resorption and formation, as is found at bone resorption sites. Tang and colleagues²⁵⁰ injected green fluorescent protein (GFP)-labeled osteogenic bone marrow stromal cells (BMSCs) into the femur cavity of *Tgfb1*^{+/+} and *Tgfb1*^{-/-} immunodeficient mice. Using anti-GFP antibodies, injected BMSCs were detected at both 1 and 4 weeks. After 1 week, BMSCs were localized to the bone surfaces in *Tgfb1*^{+/+} mice; BMSCs were widely dispersed in the bone marrow (i.e., not at bone surfaces) of *Tgfb1*^{-/-} mice. After 4 weeks, BMSCs were embedded in trabecular bone in *Tgfb1*^{+/+} mice but not in *Tgfb1*^{-/-} mice. The authors concluded that TGF- β 1 plays an essential role in the coupling of bone resorption to bone formation by their induction of osteogenic BMSCs to sites of resorption.

In addition, TGF- β expression is elevated during fracture repair²⁵¹ and has been considered for exogenous use to augment bone growth and repair. Studies support that TGF- β isoforms significantly and rapidly induce the formation of endochondral bone at extracranial sites.²⁵² Studies on the effects of TGF- β on calvarial tissue are inconclusive. Many authors have found little osteoinductive potential associated with TGF- β .²⁵³ More recently, ectopic TGF- β was shown to augment calvarial defect healing in rabbits and promote normal suture reformation.²⁵⁴ Interestingly, combination therapy of BMP-2 and TGF- β did not demonstrate increased calvarial defect repair compared to either therapy individually.

Fibroblast growth factor

The FGF family is comprised of structurally related cytokines that mediate several physiologic processes including cellular proliferation, migration, and differentiation; mitogenesis; angiogenesis; embryonic development; and wound healing. There are at least 18 known members of the FGF family, all possessing a characteristically high affinity for heparin. Most isoforms share a similar internal core region that has important FGF receptor (FGFR)-binding properties.²⁵⁵ Mutations in FGFs or FGFRs are involved in the development of various skeletal dysplasias, including achondroplasia and

craniosynostosis.³⁸ Significant evidence exists demonstrating that FGF–FGFR signaling is essential to the developing axial skeleton. Additionally, the signaling cascade is necessary for cranial bone intramembranous ossification as well as for the maintenance of cranial suture homeostasis. A review of the roles of FGF signaling in physiologic development and in the development of skeletal diseases can be found elsewhere.²⁵⁶

There are four known FGFRs (FGFR-1, -2, -3, -4). Following FGF ligand binding, receptor dimerization occurs, which promotes the transphosphorylation of each receptor monomer by an intrinsic tyrosine kinase domain. Phosphorylated tyrosine residues on FGFRs become docking sites for adaptor proteins necessary for downstream signaling.²⁵⁷ Human gene studies have identified associations between skeletal disorders and FGFR mutations, including Pfeiffer syndrome (FGFR1), Crouzon syndrome (FGFR2), and achondroplasia (FGFR3).²⁵⁶

FGF has been implicated in a variety of osteogenic mechanisms. Coffin *et al.*²⁵⁸ found that increased concentrations of FGF-2 are found at epiphyseal growth plates of endochondral bone, specifically within the proliferation and hypertrophic zones. FGF-2 also accelerates fracture repair and closure of critical-sized defects.²⁵⁹ Interestingly, there seems to be a differential effect of FGF-2 treatment based on delivery. Continuous FGF-2 treatment stimulates osteoblast proliferation; however, it decreases levels of differentiation markers (e.g., ALP) and augments osteoclast formation, thus resulting in net bone resorption. In contrast, intermittent FGF-2 treatment enhances bone formation.

The effects of FGF-2 in combination with other growth factors have also been reported. Maegawa and colleagues²⁶⁰ examined MSCs deposited in osteogenic media supplemented with BMP-2, FGF-2, or both. MSCs supplemented by both FGF-2 and BMP-2 concurrently expressed the highest levels of ALP, osteocalcin mRNA, and bone matrix formation. In addition, Sabbieti *et al.*²⁶¹ investigated whether FGF-2 modulates the anabolic response of bone to PTH. Primary calvarial osteoblasts were isolated from *Fgf-2*^{+/+} (wild type) and *Fgf-2*^{-/-} mice. By immunocytochemistry, *Fgf-2*-null osteoblasts expressed decreased Runx2 protein synthesis as well as significantly less Runx2 expression within perinuclear and nuclear spaces than wild-type variants when exposed to PTH. Given the importance of Runx2 on osteogenesis, it was concluded that *Fgf-2* expression is required for PTH to promote an anabolic response by bone.

Platelet-derived growth factor

Platelet-derived growth factor (PDGF) plays an important role in a number of biological processes, including embryological development, inflammatory reactions, angiogenesis, organogenesis, and wound healing. Four unique isoforms of PDGF have been characterized (PDGF-A, -B, -C, -D), which are inactive in their monomeric forms, and thus must dimerize to become active. Five dimeric PDGF compounds have been identified (PDGF-AA, -BB, -CC, -DD, and -AB).²⁶² All PDGF molecules share a highly conserved PDGF/vascular endothelial growth factor (VEGF) homology domain, a motif also found in VEGF.²⁶³ PDGFs interact with two receptor tyrosine kinases (PDGF receptor- α (PDGFR- α) and PDGFR- β), which also must dimerize to activate.²⁶⁴ Receptor

dimerization results in autophosphorylation at a specific tyrosine residue on a PDGFR, a necessary step for signal transduction to proceed. Because of unique temporospatial expression patterns, it is believed that PDGFR- α and PDGFR- β mediate distinct events during development.²⁶⁵

PDGF is a potent mitogen and chemotactic agent for cells and tissues of mesenchymal origin and is crucial in bone homeostasis and repair. At sites of bone fracture, platelets congregate and release PDGF. PDGF attracts many other cell types important for tissue repair and the formation of granulation tissue. PDGF has also been shown specifically to attract osteogenic cells derived from calvaria, periosteum of long bones, trabecular bone, and BMSCs.²⁶⁶ Additionally, angiogenesis is crucial for bony healing (to be discussed later) and PDGF, in addition to its direct mitogenic effect on osteoblasts, indirectly enhances bone regeneration by stimulating angiogenic cytokines.²⁶⁷

PDGF also stimulates bony healing via interactions with other growth factors. Levi *et al.*²⁶⁸ showed that IGF-1 exposure promoted osteogenic differentiation of human adipose-derived stromal cells but PDGF-A alone did not. In combination, IGF-1 and PDGF-A enhanced osteogenesis to a greater degree than IGF-1 alone, possibly due to enhanced IGF-1 transcription in the presence of PDGF-A.

The effects of PDGF on osseous repair in the clinical setting have recently been investigated. One randomized controlled trial assessed the effectiveness and safety of administering recombinant human PDGF-BB (rhPDGF-BB) with beta-tricalcium phosphate (β -TCP) for periodontal osseous defects.²⁶⁹ Compared to β -TCP, β -TCP in combination with rhPDGF-BB significantly enhanced linear bone growth (LBG) and percent defect fill at 6 months. Subjects receiving rhPDGF-BB also demonstrated a significant gain of clinical attachment level (CAL) versus those who did not. These early data were promising and therefore the authors extended the study to test long-term stability and efficacy of PDGF-BB. After 36 months, an analysis of 83 subjects with localized severe periodontal osseous defects demonstrated that, based on composite outcomes for CAL gain and LBG, PDGF-BB in a synthetic scaffold matrix promotes long-term stable clinical and radiographic improvements.²⁷⁰ Another randomized pilot study offered rhPDGF-BB within a β -TCP matrix to patients in need of ankle/hindfoot fusion.²⁷¹ Compared to subjects receiving autologous bone grafting, the PDGF group demonstrated greater osseous bridging across the fusion site.

Healing of fractures

Bone repair is the physiologic process by which the body facilitates the healing of fractures. In many ways, fracture repair recapitulates the events that occur during skeletogenesis. Successful fracture healing is dependent upon many factors. The mechanism of disruption, the fracture pattern, and the method and timing of fixation all affect the outcome of bone repair. For example, fractures that create more than two fragments of the same bone (comminuted fractures) require swift surgical intervention to heal successfully. In addition, the biologic milieu surrounding a fractured bone may play a role in the fate of the fracture.

Originally distinguished based on their histology, two types of bone repair have been described (Fig. 18.4). Primary

Fig. 18.4 Schematic representation of primary and secondary (callus) bone repair. (A) Primary bone repair: nondisplaced bone fragments heal without cartilaginous intermediate. (B) Secondary (callus) bone repair: displaced (or unstable) bone segments heal with cartilaginous intermediate. (Modified from Mehrara BJ, McCarthy JG. *Repair and grafting of bone*. In: Mathes SJ, ed. *Plastic Surgery*. Vol. 2. Philadelphia: WB Saunders; 2005:639–718.)

bone repair refers to direct cortical healing of two fracture ends without a cartilaginous intermediate. In contrast, during secondary (callus) bone repair, a cartilaginous intermediate is formed by mechanisms that occur within the periosteum, soft tissues, and bone marrow. Most fracture repair is by secondary bone healing.

Primary bone repair

Primary bone repair involves the direct deposition of woven bone by osteoblasts to re-establish mechanical continuity between fracture fragments. Similar to intramembranous ossification, the periosteum provides osteoprogenitor cells and undifferentiated MSCs during primary bone repair. In order for primary repair to occur, fracture fragments are reduced to anatomic position, usually by rigid internal fixation. The interfragmentary strain should also be at a minimum.²⁷² Bone healing occurs under axial compression and fails under tension (Fig. 18.5).

During primary bone repair, new bone is synthesized in parallel to the long axis of the bone by osteoprogenitor cells. This process is initiated by the formation of cutting cones at

Fig. 18.5 The compression mode of miniplate fixation. **(A)** A four-hole plate. Note that the inner holes are eccentrically shaped so that, as the screws are tightened, the head falls into the wider portion and compresses the bone margins **(B)**. **(C)** Completed view of the skeletal fixation.

the junction of live and necrotic skeletal segments. A cutting cone is a system of cells, mainly composed of active osteoclasts. It burrows its way through cortical bone across the fractured bone segments, thereby allowing the ingrowth of blood vessels and undifferentiated MSCs. MSCs then differentiate into bone-producing osteoblasts. New haversian systems are created and provide pathways for blood vessel penetration. Initially, bone is laid down in a woven-matrix configuration. Within a few weeks, the woven bone becomes more lamellar-like in its orientation. As the proportion of lamellar bone increases over the course of months, complete fracture repair occurs. The benefits of rigid plate osteosynthesis include increased stability, decreased incidence of non- and

malunion, and decreased incidence of infection.²⁷³ Orthopedic and cardiac surgeons commonly perform rigid internal fixation.²⁷⁴ Reconstructive surgeons also use rigid fixation techniques to repair or reconstruct the craniofacial skeleton.^{275,276}

Secondary (callus) bone repair

Untreated fractures or those treated with external or intramedullary fixation or by sling or cast immobilization (i.e., without rigid fixation) heal by secondary repair. During secondary or callus bone repair, colonies of MSCs form cartilage at the fracture prior to bone formation. There are three overlapping phases of secondary repair: inflammatory, reparative, and remodeling (Fig. 18.6). However, at least five distinct stages have been described.²⁷⁷

After a fracture, the disruption of osseous, soft, and vascular tissues initiates the inflammatory phase. Lasting roughly seven days, the inflammatory phase peaks at approximately 48 hours post-injury. Pain and swelling during this time promote immobilization at the fracture site.²⁷⁸ A hematoma forms, further immobilizing the area via its fibrin network. The hematoma is also a source of signaling molecules that initiate repair.²⁷⁹ Platelets release PDGF and TGF- β , which promote MSC proliferation and osteogenic differentiation. Recruited neutrophils, lymphocytes, monocytes, and macrophages remove necrotic debris and stimulate angiogenesis.

Approximately 3–4 days post-fracture – before the inflammatory phase subsides – the reparative phase commences. This phase lasts weeks to months and is characterized by the development of a fracture callus that will stabilize and unite fracture segments before being replaced by bone. The callus is chiefly composed of cartilage, but also contains woven bone, osteoid, fibrous connective tissue, and blood vessels. MSCs from the surrounding periosteum and marrow migrate to the injured site and mature into many cell types, including osteoblasts, chondrocytes, and fibroblasts, which form the callus.

The fracture callus undergoes both intramembranous and endochondral ossification.²⁷⁷ Endochondral ossification occurs during the second week of repair, when abundant cartilage overlying the fracture site (formed by chondrogenesis of the callus) undergoes calcification. Blood vessels grow into this calcified cartilaginous callus, bringing with them osteoblast progenitor cells. As the calcified cartilage is resorbed by chondroclasts, osteoblasts begin to lay woven bone. Intramembranous ossification, on the other hand, occurs adjacent to the fracture site.

The remodeling phase is characterized by the replacement of woven bone with lamellar bone and may remain active for several years. Osteoclasts resorb poorly located trabeculae and new bone is formed along the lines of stress. In response to varying mechanical loads, bone will gradually modify at the fracture region until optimum regeneration is achieved. During remodeling, pain subsides and the normal activities can be resumed.

Variables influencing bone repair

Blood supply

Blood flow to bone represents approximately 10–20% of total cardiac output. The pattern of vascularization to the majority of the appendicular skeleton is similar in organization to the

Fig. 18.6 Schematic diagram of callus fracture repair in endochondral bone. **(A)** Early stages of fracture repair characterized by hematoma formation, inflammatory cell migration and differentiation (polymorphonuclear neutrophils), and scattered primitive mesenchymal cells. **(B)** As healing progresses, a callus is formed between the bone edges, and hypertrophic chondrocytes can be seen. In addition, newly formed blood vessels sprout from the nutrient artery and local blood vessels. **(C)** Primitive woven bone has bridged the fractured bone segment. **(D)** Woven bone is remodeled into lamellar bone.

vascular pattern of a typical long bone.²⁸⁰ A tubular long bone in the adult human receives blood by three distinct arterial systems that interconnect extensively with one another (Fig. 18.7). The primary blood supply to the inner two-thirds of bony cortex and the medullary cavity comes from the diaphyseal nutrient artery. As the nutrient artery traverses the cortex, it passes through to the medullary cavity, where it divides into ascending and descending medullary branches. Metaphyseal and epiphyseal arteries represent the second significant source of blood. These vessels arise from arteries supplying adjacent joints and deliver blood to cancellous bone found at the end of long bones. The third main source of blood comes from periosteal arteries, which carry supply to the outer one-third of cortex.

Fig. 18.7 The three sources of blood supply to the long bone. The nutrient artery provides the principal source of blood supply to the marrow cavity and the inner cortex. The diaphyseal periosteal vessels supply the outer cortex of the diaphysis. The metaphyseal epiphyseal periosteal vessels penetrate the cortex of the bone in the adult and anastomose with the nutrient artery, providing adequate supply to the marrow cavity and inner cortex in cases of disruption of the nutrient artery.

As blood travels through bone from endosteum to periosteum, it flows through sinusoids and arterioles within the haversian system. Exchange vessels (i.e., vessels connecting the arterial and venous systems) within osteons lie parallel to the axis of the bone. Collecting sinuses and veins with similar names to their arterial counterparts receive deoxygenated blood from exchange vessels. A high intramedullary pressure

is likely responsible for the centrifugal flow of blood through bone.²⁸¹

Angiogenesis is critical for bone maturation and repair.²⁸² Although the mechanisms that regulate angiogenesis during fracture repair have not been fully elucidated, many important angiogenic cytokines have been described (Table 18.4). One molecule thought to play a pivotal role in angiogenesis within

Table 18.4 Growth factors and angiogenesis

Growth factor	Structure	Angiogenesis	Function	Role in fracture healing	Regulation of expression	Receptor
BMP	Single large propeptide molecule Cleavage enables dimerization Member of the TGF- β superfamily Conserved series of seven cysteine residues at carboxyl terminal At least 15 known isoforms	Indirect regulator of angiogenesis	Mitogen and chemoattractant for osteoblasts and mesenchymal cells Apoptosis Patterning	Expressed by mesenchymal cells early in fracture repair Also expressed by osteoblasts and osteoclasts Exogenous BMPs can heal critical-sized defects Ectopic bone formation ? Accelerate fracture repair ? Actions synergistic with TGF- β	Patterning genes and transcription factors (e.g., Cbfa1)	Serine-threonine kinase receptors
TGF- β	Propeptide Cleavage necessary for activation At least three different isoforms	Indirect regulator of angiogenesis	Chemoattractant and mitogen for osteoblast precursors and osteoblasts Inhibits osteoblast differentiation Regulates expression of other growth factors important in angiogenesis and osteogenesis Increases matrix synthesis	Produced for osteoblasts, mesenchymal cells, osteoclasts Increases callus formation and volume Subperiosteal injection promotes both chondrogenesis and membranous ossification Exogenous TGF- β may heal some critical-sized defects	Patterning genes and transcription factors Mechanical strain	Serine-threonine kinase receptors
FGF-2	Heparin-binding glycoprotein At least nine different isoforms	Direct regulator of angiogenesis	Angiogenesis Regulator of bone development and skeletal patterning Can regulate osteoblast differentiation and proliferation (actual effect is dose-dependent)	Increases angiogenesis in fracture site Increases expression during fracture repair Exogenous FGF-2 can increase mechanical strength of fractures ? Accelerates fracture repair or promotes healing of critical-sized defects	Inflammatory cells and acute inflammation Patterning genes and transcription factors	Tyrosine kinase receptors

Table 18.4 Growth factors and angiogenesis—cont'd

Growth factor	Structure	Angiogenesis	Function	Role in fracture healing	Regulation of expression	Receptor
VEGF	Dimeric glycoprotein	Direct regulator of angiogenesis	Increases vascular permeability Increases vascular sprouting Increases endothelial cell migration, proliferation, adhesion	Increased expression during fracture repair Expressed by osteoblasts, osteoclasts, and mesenchymal cells Increases blood vessels in growth during fracture repair	Microenvironment (e.g., pH, hypoxia, lactic acid concentration) Growth factors (e.g., TGF- β , FGF, BMP, IGF), inflammatory cytokines (e.g., PGE ₂)	Tyrosine kinase receptors
PDGF	Dimeric, disulfide-bonded polypeptide chain α and β subunits determine isoform (AA, AB)	Indirect regulator of angiogenesis	Promotes chemotaxis of osteoblasts and inflammatory mediators Decreases cellular differentiation Increases collagen synthesis Increases collagen degradation and turnover May promote osteoblast proliferation	Released by degranulating platelets and acts to increase osteoblast chemotaxis, and possibly proliferation Expressed by osteoblasts, macrophages, and mature/immature chondrocytes during fracture repair Promotes synthesis of angiogenic molecules (e.g., VEGF) Promotes matrix deposition and turnover	Inflammation and injury Mechanical strain TGF- β (decreased expression)	Tyrosine kinase receptors

BMP, bone morphogenetic protein; FGF-2, fibroblast growth factor; IGF, insulin-like growth factor; PDGF, platelet-derived growth factor; PGE₂, prostaglandin E₂; TGF- β , transforming growth factor-beta; VEGF, vascular endothelial growth factor.

developing and healing bone is VEGF. Other factors described previously (BMP, TGF- β , FGF-2, and PDGF) have also been implicated in angiogenic processes necessary for osteogenesis. VEGF and FGF-2 are the only two directly acting regulators of angiogenesis; other growth factors serve indirect roles. In addition, the hypoxia-inducible factor-1 α (HIF-1 α) pathway is crucial to the coupling of angiogenesis with osteogenesis.²⁸³ Discoveries associated with this pathway have led authors to hypothesize that skeletal angiogenesis and osteogenic-angiogenic interactions are rate-limiting processes in bone growth.

A potent regulator of both vasculogenesis and angiogenesis, VEGF mediates many important functions during the embryologic stage of development and throughout the lifetime of organisms. Deletion of a single VEGF allele is associated with lethality *in utero*.²⁸⁴ VEGF is structurally related to PDGF and is expressed by many cell types, often at high concentrations within highly vascularized tissues. VEGF mediates its effects on cells through interactions with VEGF receptors (VEGFR-1, VEGFR-2, VEGFR-3).

The hypothesis that VEGF plays an essential role in skeletogenesis mainly comes from studies examining endochondral bone formation. At the epiphyseal growth plates of long bones, hypertrophic chondrocytes express high levels of VEGF.²⁸⁵ Injection of an anti-VEGF monoclonal antibody

results in inhibition of vascular invasion of the nonhuman primate growth plate, thereby hampering longitudinal bone growth.²⁸⁶ Moreover, mice treated with a VEGF inhibitor manifest significantly decreased bone capillary invasion and trabecular bone formation.²⁸⁷ Cessation of anti-VEGF treatment is associated with capillary invasion and restoration of bone growth. A comprehensive review produced by Yang *et al.*²⁸⁸ discusses VEGF in the context of bone angiogenesis and development, emphasizing its role on intramembranous and endochondral ossification.

The therapeutic utilization of VEGF and other angiogenic cytokines is a subject of great promise in the treatment of patients with both complicated and uncomplicated fractures. Luo and colleagues²⁸⁹ examined the effects of VEGF and BMP-2 on bone defect repair around dental implants. The study found that bone marrow stromal cells within chitosan/collagen scaffolds were responsive to AdBMP-2 administration but VEGF alone failed to stimulate bone formation. Administration of AdBMP-2 and VEGF protein together resulted in significantly increased bone formation and bone-to-implant contact compared to the AdBMP-2 group, suggesting a synergistic effect of combination BMP-2 gene and VEGF protein therapy on bone healing. In addition, Liu and Olsen²⁹⁰ found that mice with a congenital deficiency of VEGF in osteoblastic precursor cells demonstrate reduced bone mass

and increased bone marrow fat consistent with an osteoporosis-type phenotype. Therefore, VEGF has become a potential target for therapies to reduce bone loss.

Fracture fixation

Critical to the success of fracture repair in long bones is the extent of movement at the fracture site after fixation.²⁹¹ Delayed union and nonunion are both associated with excess motion; however, some movement, known as micromotion, can enhance bone healing. The mechanism by which absolute immobilization hampers fracture repair may be related to increased resorption in a stress-protected environment. In addition, the degree of mechanical strain endured at the site of a fixed fracture has differential effects on chondrogenesis and osteogenesis.²⁹²

Age

Characteristic changes within bone occur during the aging process. Pediatric fractures tend to heal at an accelerated rate compared to adult fractures.²⁹³ This may in part be due to the effect of age on angiogenesis.²⁹⁴ To understand this, Lu and colleagues²⁹⁵ evaluated tibial fractures created in 4-week-old, 6-month-old, and 18-month-old (juvenile, middle-aged, and elderly, respectively) rats. At 7 days post-fracture, there was a higher surface density of blood vessels in juvenile fracture calluses compared to middle-aged and elderly rats. In addition, juvenile rats expressed increased HIF-1 α and VEGF at 3 days post-fracture versus older rats. These data support the notion that angiogenic potential during fracture healing changes over time. Age may also influence fracture repair via effects on periosteal structure, cell population and chondrogenic potential; stem cell function; and biologic signaling.^{296,297}

Bone remodeling

Osteoinduction

Osteoinduction is a process by which undifferentiated pluripotent cells are stimulated to become cells within the osteoblast lineage.²⁹⁸ It occurs naturally during skeletogenesis and fracture repair.

Although osteoinduction is an intrinsic biologic process, it can also be manipulated exogenously. For example, purified and recombinant human isoforms of BMP are commonly used in experimental settings to induce bony formation. Various biomaterials have also been used for the same purpose. Bioglass and other osteoinductive materials have shown promise when used in craniomaxillofacial applications.²⁹⁹ After bioactive glass is mixed with saline or blood, an apatite surface layer forms at the biomaterial–bone interface, which incorporates collagen and proteins from surrounding native bone. In addition to producing a chemical bone at the interface, the apatite layer stimulates production of osteogenic cytokines from surrounding osteoprogenitor cells, resulting in new bone formation.³⁰⁰

A major concern in the treatment of significant osseous defects is the amount of native tissue available for repair. Large defects may not be amenable to autologous reconstruction without undue donor site morbidity. Therefore, an area of intense study is the identification of undifferentiated cells that

differentiate to produce bone when exposed to osteoinductive factors. Significant quantities of these progenitor cell types are found in adipose tissue¹⁹¹ as well as the neonatal umbilical cord and infant palatal periosteum.³⁰¹ The ability to harvest and manipulate these cells via osteoinduction has important therapeutic implications for both children and adults suffering critical-sized bony defects.

There are numerous strategies to facilitate the osteoinduction of effector cells in order to produce bone. Examples include the use of bone grafts, vascularized bone flaps, bioactive scaffolds, osteogenic growth factors, and biophysical stimulation.³⁰² A detailed discussion of bony regeneration and osteoinduction can be found elsewhere.^{303,304}

Osteoconduction

Osteoconduction is the ability of a material to serve as a scaffold onto which bone can attach and grow. During primary bone repair, the opposing fracture fragments mediate osteoconduction. In secondary bone repair, callus ECM acts as a scaffold onto which new bone can attach and develop. In the field of regenerative medicine, many implanted materials serve an osteoconductive role. An osteoconductive substrate must be porous to allow for the ingrowth of bone and fibrovascular tissue during osteoinduction.³⁰⁵ Many osteoconductive materials are available to enhance bony healing in the clinical setting. Reconstructive surgeons can choose from allografts (processed human bone), autogenous bone grafts, purified collagen, calcium phosphate (CaP) substitutes, synthetic polymers, and more. In some cases, osteoconductive materials may also have osteoinductive properties. Native bone, for example, stimulates both osteoconduction and osteoinduction. Additionally, purely osteoconductive materials (e.g., CaP substitutes) are enhanced by being combined with osteoinductive factors (e.g., BMP) before placement into a defect.³⁰⁶

Osseointegration

The phenomenon of osseointegration describes a stable anchorage between bone and implant that results in a structural and functional connection between the two. Similar to primary fracture healing, during osseointegration native bone and the implant unite without a cartilaginous intermediate. A key difference between primary fracture repair and osseointegration is unification of native tissue and a foreign body during osseointegration. Therefore, the structure and composition of the implant are integral to the process.

In order for osseointegration to manifest, certain prerequisites must be met.³⁰⁷ The implant must be bioinert or favorably bioactive. Bioinert materials do not cause adverse reactions in native tissue. Titanium is an example of a bioinert material often used in dental, craniofacial, and orthopedic procedures. A material that is favorably bioactive promotes a positive tissue reaction by facilitating osseous tissue production or chemical bond formation between implant and native tissue. Favorable bioactive agents are often used to coat implants with an otherwise unfavorable mechanical quality. The degree and strength of bone–implant contact depend on the surface properties of an implant. The extent of bone–implant interface has been shown to be positively correlated to implant surface roughness.³⁰⁸ A rougher implant may be better able to tolerate

shear stress. In addition, Butz and colleagues³⁰⁹ assessed the intrinsic biomechanical properties (hardness and elastic modulus) of bone tissue integrated to titanium implants with varying degrees of surface roughness. Bone deposited around acid-etched titanium implants displayed enhanced biomechanical properties compared to bone deposited around implants with smoother, machined surface topography. Similarly, compared with machined surfaces, implant surfaces subjected to anodization exhibit increased bone-to-implant contact.³¹⁰

Distraction osteogenesis

Distraction osteogenesis, the formation of new bone from the gradual separation of osteotomized fronts, was pioneered by the work of Codvilla at the turn of the 20th century and expanded by Ilizarov in orthopedic surgery.^{311–313} Through a set of rigorous experimentations, Ilizarov³¹³ was the first to establish the hypothesis that gradual controlled separation of osteotomized bone results in a “tension stress effect” leading to angiogenesis and new bone formation. These initial observations and classic experiments were based upon the axial skeleton. It was not until the early 1970s that the concept of craniofacial distraction was introduced, first in a canine model,³¹⁴ in which the authors demonstrated correction of an iatrogenic crossbite by an external distraction device (1 mm/day for 2 weeks). The application of distraction to the human craniofacial skeleton was finally introduced by McCarthy *et al.* in the early 1990s.^{315–317} Since its inception in the human mandible, the indications of distraction osteogenesis have expanded from congenital cases to cases of craniofacial skeletal deficiency with tumor-, trauma-, or iatrogenic-related etiologies.

Distraction osteogenesis requires three main stages for successful augmentation of bone formation: latency, activation, and consolidation. The first stage, latency, occurs immediately after osteotomy and refers to the period during which bone healing is initiated at the bony gap, periosteal integrity is restored, and callus formation begins. Latency typically ranges between 1 and 7 days, and is typically gauged according to the patient's age; the younger the patient, the shorter the latency period. During the second stage, activation (distraction), osteogenesis is induced with the generation of immature bone. Distraction occurs by the turning of an axial screw at a predetermined rate for a certain number of days until target bone augmentation is achieved. The third and final stage, consolidation, refers to the phase during which immature bone remodels into mature bone. In practical terms, consolidation is the period from the end of distraction to the removal of the device. The parameters for these stages are established by the craniofacial surgeon in response to specific patient profiles and the region of the skeleton undergoing distraction.

As understanding of and experience with distraction osteogenesis advance, associated adverse events occur less frequently.³¹⁸ However, this number may be underreported.^{319,320} Complications that arise may be due to surgeon technique, patient factors (see below), hardware failure, or unknown factors. Many authors have attempted to classify complications for specific body areas (e.g., mandibular distraction)^{318,320–322}; however, no consensus standard classification scheme exists.

Histology

Successful distraction osteogenesis results from membranous ossification in the absence of a cartilaginous intermediate.^{323–327} In the early phases of regenerate formation, distraction angiogenesis is a more accurate term to describe the cellular response to ischemia and traction. This phase is characterized by the appearance of multipotent precursor cells and type I collagen matrix expression in the distraction zone. Recently, Cetrulo and colleagues were able to demonstrate the honing of MSCs to the distraction zone in rat mandibles after intra-arterial transfer,³²⁸ an indication that paracrine factors expressed in ischemia (e.g., HIF-1 α) are chemoattractants and eventual agents of osteoinduction. Specifically, endothelial precursor cells are enriched at midactivation through 1–2 weeks into the consolidation period, when distracted rats were compared to controls.³²⁸ CD31, CD34, and Flk-1, markers of neovascularization, stem cells, and endothelial precursors, respectively, have all been demonstrated by immunohistochemistry. Further in the activation period, dense collagen fibrils are formed and organized in the direction of distraction as a template for mineralization.^{325,329–331}

It has been recognized that bone precursor cells respond to mechanical cues in order to differentiate. Distraction appears to be no exception to this tenet. In a rat model, Rhee and colleagues demonstrated increased intranuclear expression of signal transduction factors ERK1/ERK2 early in the distraction phase.³³² This expression paralleled upregulation of BMP-2/BMP-4, two relatively potent osteoinduction agents. Mineralization by active mature osteoblasts starts 10–14 days after the onset of distraction, and begins at the osteotomy fronts, proceeding centrally towards the relatively avascular fibrous interzone (Fig. 18.8).^{313,325,329,333} This leads to the formation of the primary mineralization front. Thin-walled vascular channels and bony spicules are slowly converted to normal lamellar bone and marrow. Interestingly, during the latter phase of activation, the infantile regenerate is still malleable and can remodel according to external forces. One can therefore take advantage of the gradual process and judiciously manipulate the distracted bone clinically in order to obtain a more precise occlusion, for example. This clinical principle, which is based on the gradual histomorphogenesis of the distraction zone, is termed molding the regenerate.^{334,335} Several studies have confirmed that molding the distraction bone, clinically by use of an orthopedic appliance, does not lead to disturbance of the regenerate or fibrous nonunion.^{334,335}

Variables affecting osteogenesis

To understand the variables that have a negative or positive impact on osteogenesis in the context of distraction, one must understand the factors that promote successful regenerate formation and bony union. These tenets are aptly described by Ilizarov³³⁶: (1) device stability; (2) a latency period; (3) a gradual distraction (activation) period; and (4) a sufficient consolidation period. First, osteocyte viability reflects osteoblastic activity and thus the selection of a strong area of bone for osteotomy and distractor placement is critical. A stable device placed in stably healing bone results in the formation of strong cortical bone within the regenerate and minimizes the chance of fibrous nonunion. It follows that any thermal or mechanical injury to the bone can damage the blood supply to the bone, resulting in

Fig. 18.8 Schematic drawing of bone formation during distraction osteogenesis. After approximately 10 days of distraction and during the distraction period, the regenerated tissue can be divided into three zones: (1) an avascular fibrous interzone (FZ); (2) two mineralization zones (MZ) or fronts; (3) and two regenerate zones (RZ). Regenerate zones are adjacent to residual host bone segments (RHBS). (From Samchukov ML, Cope JB, Cherkashin AM. *Craniofacial Distraction Osteogenesis*. St. Louis: Mosby; 2001.)

ischemic fibrogenesis. Fibrogenic damage leads to irregular and disorganized collagen formation from arterial insufficiency or cystic degeneration from venous outflow obstruction. Previous concerns of periosteal damage resulting in poor osteogenesis have recently diminished as increasing experience among craniofacial surgeons has demonstrated that, even with complete osteotomy, the periosteum is sufficiently osteogenic for strong bone production.

Inappropriate timing of the distraction stages can result in osteogenic failure. In terms of the latency period, this translates into either too short a period (immediate distraction) or a prolonged period (delayed distraction). Important for primordial callus and ultimately regenerate volume, latency periods range between 0 and 7 days, depending upon patient variables, such as age, osteotomy site, blood supply, and other factors that may affect regenerate formation (see below). The majority of experimental evidence points to an optimal latency period of 5–7 days. Theoretically, immediate distraction may prevent adequate hematoma and primordial callus generation, culminating in a regenerate of suboptimal volume/mechanical strength, and, in extreme circumstances, fibrous nonunion. It follows that disruption of initial fracture hematomas, which simulates an abbreviated latency period, results in a 26% decrease in callus cross-sectional area, and a significant impairment in the mechanical strength of the newly formed bone.³³⁷ On the other hand, deferment of the distraction period >14 days results in premature consolidation of the distraction site and device failure.^{323,329,338,339}

Overall, latency periods have been a source of debate among craniofacial surgeons and their significance held in question ever since the inception of the technique. To this end, studies comparing latency periods of 7, 14, and 21 days have

failed to underscore any difference in protocols in terms of osteogenesis.^{340,341} Clinically, Hollier and colleagues demonstrate a low complication rate with the elimination of the latency period and implementation of a rapid distraction rate (2 mm/day) in their pediatric population.³⁴² It is important to note that the nonunion rate in this series was 4.5% and was attributed to the only distracted bone graft in the study. It is generally accepted that reduced latency periods and faster distraction rates formulate an acceptable protocol in children, due to improved blood supply and osteogenic potential. A study by Slack *et al.*³⁴³ showed that children (ages 4–12) undergoing mandibular distraction demonstrate no difference in clinical outcomes up to one year postoperatively whether their distraction protocol contains a 48-hour latency period or no latency period. Flexibility in the timing and rate of distraction needs to be inherent in any successful protocol, with respect to patient profile.

Patient factors

Age

It has been well recognized that increasing age contributes negatively to the overall outcome of distraction osteogenesis, presumably secondary to limited ability of older subjects to recruit osteoprogenitor cells to the site of injury. In support of this concept, studies have demonstrated that the rate of bone formation and bone mineral deposition in pediatric distraction patients (385 mm/day) is far superior to adults (213 mm/day).³⁴⁰ This age-related difference in osteogenic potential, however, is not a contraindication to distraction osteogenesis, as older individuals can undergo surgery successfully. In this context, latency and consolidation periods may be extended to allow for protracted regenerate formation in the older patient.

Blood supply

Several studies have demonstrated that, on a molecular level, the establishment of neovascularization is critical to the formation and eventual mineralization of the regenerate. Accordingly, factors that impair vascularization of the distracted field may result in failed bone formation. Osteocyte survival depends on the proximity of less than 0.1 mm to nutrient vessels.³⁴⁴ The factors critical in osteogenesis of the axial skeleton (e.g., periosteal preservation) appear to be less important for osteogenesis in the craniofacial skeleton.^{312,323,333,337,339,345,346} There are, however, factors that unify both regions.

Radiation/chemotherapy

Radiotherapy, by compromising vascularity, cellularity, and local oxygen supply, has been known to impair osteogenesis. Limited clinical^{347–349} and animal studies^{350–353} have been performed in this regard; these studies have had mixed results. In the experimental realm, animals exposed to 36 Gy of radiation prior to the distraction process show a definitive decrease in bone mineralization microdensitometric analysis.³⁵⁴ These authors therefore propose finding an optimal radiation dosing protocol, which would make distraction osteogenesis a viable alternative in the head and neck cancer patient. Regardless of the optimal conditions for radiation delivery and in consideration of the reduced vascularity within the irradiated field,

such patients may need an extended latency period, slower distraction rate, and longer consolidation period to achieve similar outcomes in osteogenesis to the nonirradiated patient.

Many patients with malignant bone tumors will receive chemotherapy as part of their treatment plan. Chemotherapeutic agents are often cytotoxic not just to tumor cells but also to normal cells. Timing appears to be important with respect to the detrimental effects of chemotherapy on bone formed by distraction osteogenesis. Monsell and colleagues³⁵⁵ found in distracted rabbits that preoperative chemotherapy reduced regenerate bone mineral density, bone mineral content, and volumetric bone mineral density but did not alter regenerate structural integrity (i.e., the callus formed is of good quality). In contrast, perioperative chemotherapy does not alter bone mineralization but negatively impacts mechanical properties including energy at yield and yield strain.^{355,356} The latter may have clinical implications and further studies in humans are required.

Clinical application of bone transfers

Indication for bone transfers

A variety of clinical approaches are currently used to repair skeletal defects in plastic surgery. In order to provide an optimal outcome, detailed analyses of the bony defect and mechanical requirements of the reconstructed part are needed. Reconstruction of bony deficiencies can be performed using autografts (obtained from the patient), allografts (obtained from another individual), xenografts (obtained from another species), bone substitutes, or implants. The ideal is to use autologous bone grafting when possible. The type of bone graft is chosen based on the clinical scenario; medical condition of the patient; previous radiation, infection, or severe scarring of the recipient site; donor site availability; and patient and surgeon preference.

Common indications for the use of bone grafts are critical-sized bony defects from trauma, tumor resection, and congenital disease. Other indications include fracture nonunion, arthrodeses, limb-lengthening procedures, and spinal fusion. The structure and biomechanical properties of the graft determine the clinical application.

Bone graft healing and graft survival

Bone graft incorporation and fracture healing go through similar stages. Graft incorporation consists of graft resorption and replacement by vascular ingrowth and new bone (i.e., creeping substitution).³⁵⁷ Bone graft incorporation is subject to several factors: type of graft (e.g., autogenous/allogeneic, vascularized/nonvascularized), quality of transplanted bone and recipient site, mechanical properties of the graft, and systemic and local disease. The molecular and mechanical environment of the graft site, the contact between the graft and recipient bed, and the osteoinductive, osteoconductive, and osseointegrative capability of the graft influence bone graft healing.

Bone formation during remodeling is stimulated by compression, which leads to periosteal and endosteal apposition; traction, in contrast, promotes periosteal resorption and

intracortical osteolysis.³⁵⁸ Successful grafting requires a well-vascularized bed and adequate graft fixation.³⁵⁹ Mechanical stability of the healing defect allows for revascularization of the graft.³⁶⁰ Mechanical stress on a rigidly fixed graft prevents graft resorption.^{361–363} An intact periosteum also improves graft survival.³⁶¹

Cancellous versus cortical grafts

Cancellous and cortical bone grafts have different applications in skeletal reconstruction. Compared to cortical bone, cancellous bone has little immediate strength or structural support but has higher osteogenic, osteoinductive, and osteoconductive properties. It is more quickly incorporated and revascularized than cortical bone, usually within two weeks. In the transplanted cancellous bone graft, viable osteoblasts and endosteal cells line the graft surface. Cancellous bone grafts serve as an osteoconductive substrate to support creeping substitution.^{364–367} They are indicated to bridge gaps less than 6 cm in nonstress-bearing areas. Typical sources of cancellous bone grafts are iliac crest, cranial diploe, upper tibial epiphysis, and distal radius.

Cortical bone, alternatively, has limited osteogenic potential.³⁶⁸ Creeping substitution is the main mechanism of cortical bone graft incorporation, and the graft largely relies on plasmatic imbibition from the recipient bed to support the outer layer of osteocytes.³⁶⁵ The incorporation and revascularization of cortical grafts usually take one to two months.^{369–371} However, cortical grafts provide immediate structural support and are able to bridge defects up to 12 cm. Cortical grafts should be tailored to the defect. Generally, rigid fixation is required to prevent fracture of the healing graft.³⁷² Cortical grafts are often used for onlay augmentation of contour deficits. Typical graft sites include fibula, rib, and iliac crest.

Clinical considerations

To optimize the chance of survival, the bone graft should be handled as follows³⁷³:

1. Graft exposure time to air at room temperature should be minimized (ideally to less than one hour to maintain cell viability).³⁷⁴ However, longer periods of ischemia can be tolerated by bone cells if the medullary nutrient blood supply is later reconstituted, as in vascularized bone.³⁷⁵
2. To enhance bone viability by four to six hours, a graft should be covered in a blood-soaked sponge with a moist saline gauze on top. If longer periods of graft exposure are required, cell viability can be maintained if the graft is stored in 10% human serum albumin and a 90% balanced salt solution at 3°C in Collins–Terasaki solution.³⁷⁵
3. Grafts should be kept cool, as temperatures over 42°C may cause cell death.
4. Antibiotic washes are not only bactericidal but are also cellucidal and therefore should be used with caution.
5. Dead space around the graft should be avoided.
6. The cancellous portion of the graft should be placed in contact with the cancellous bone in the bed.
7. Ideally, the graft should be placed in a previously prepared vascularized bed to increase graft survival.

Taking the iliac-bone graft. *J Bone Joint Surg Am*. 1978;60:411.)

Techniques of harvest: autologous bone grafts

Ilium

The ilium is the most commonly used site for corticocancellous bone grafts (Figs. 18.9, 18.10). The clinical indications are wide due to the versatility of the ilium, the large amount of cortical and cancellous bone available, and the possibility to transfer it as a vascularized bone flap. The iliac crest is easily accessible and has limited morbidity if proper technique is employed. Complications include chronic donor site pain, paresthesias, and gait abnormalities.³⁷⁶

The harvest technique should preserve the shape of the iliac crest by careful and proper splitting. Correct handling of the iliac wing permits its regeneration and allows for further or repeat harvest. Additionally, wiring the split iliac crest back together can decrease postoperative pain. Care must be taken to avoid stretching the lateral femoral cutaneous nerve by unnecessary superior dissection, to avoid tearing the gluteal muscles, and to avoid removing the iliac crest itself.

Preservation of the insertion of the abdominal and gluteal muscles on the iliac crest is key. Dependent upon the amount of graft taken, the outer, inner, or both cortical plates of the iliac wing need to be preserved. The amount of cancellous bone that can be harvested from the ilium is quite large – down to the cotyloid ridge above the glenoid fossa. A large subcrest corticocancellous graft up to 11 cm, a 6×10 cm corticocancellous inner plate, and an approximately 5×8 cm corticocancellous outer plate can also be harvested. Harvest of the anterior iliac crest (see Fig. 18.9) is convenient due to supine patient position. However, the posterior iliac crest provides a larger amount of graft and avoids aberrant entry into the abdomen. To prevent avulsion fractures of the anterior superior iliac spine (ASIS), the anterior approach should stop 3 cm posterior to the ASIS. The posterior approach should stop 4 cm anterior to the posterior superior iliac spine to prevent injury to the sacroiliac joint.³⁶⁸

The anterior approach can be performed in supine position or with a roll underneath the patient's hip to raise it. The following landmarks are drawn: ASIS and the tubercle of the iliac crest. The incision is placed over the iliac crest and is

6–10 cm in length. By pulling the skin medially, the incision actually resides 3–5 cm below and lateral to the iliac crest. No subcutaneous dissection is necessary; the abdominal soft tissue is retracted medially and the crest, tuberosity, and anterior spine are palpated. A cartilaginous cap is frequently encountered overlying the bone and this must be split to access the cortical plate. The next step is to split the iliac crest; the split is extended just behind the anterior spine. The medial leaf of the split crest is created and moved medially as a single piece with the attachments of the abdominal muscles. The same maneuver is performed for the lateral leaf with attention to the convexity of the lateral crest. The grafts are extracted according to defect size and shape.³⁷⁷ Excessive retraction can potentially cause injury to the lateral femoral cutaneous nerve, which travels retroperitoneal on the deep surface of the iliac muscle, down to the inguinal ligament near the ASIS. This can result in postoperative paresthesias.

Prior to closure, hemostasis is achieved using electrocautery or bone wax (e.g., bleeding from the central artery of the iliac bone).

Gelfoam can be placed in the periosteal pocket, and the iliac leafs are wired back together. Muscles, subcutaneous tissue, and skin are closed in a layered fashion over a suction drain. A pain pump catheter delivering local anesthetics can be inserted in the wound for better postoperative pain control.³⁷⁸ In similar fashion, the posterior iliac crest can be harvested from the supine or prone position. When harvesting this region of the crest in the prone position, one must take care to avoid injury to the cluneal nerves.³⁷⁸ Also, in order to prevent injury to the sacroiliac joint, the most posterior mark with the osteotome is made 4 cm anterior to the posterior iliac spine.³⁶⁸

Complications are rare if proper technique is used, as shown in a summary of 5600 patients with a resultant complication rate of 0.5%.³⁷⁷

Tibia and fibula

The tibia was mainly used as a source of corticocancellous bone graft during World War I and II. Its use has decreased in popularity due to donor site morbidity and pathologic fractures. The tibia remains a favorable donor site in various centers in Scandinavia and the UK when only small amounts of cancellous bone are needed (e.g., alveolar bone grafting).^{379,380} A detailed description of technical aspects of tibial harvest has been given (Fig. 18.11).³⁸¹

The use of fibula grafts has decreased with the availability of allograft. Currently, the fibula is mainly used as a vascularized transfer for mandible reconstruction, as well as midface and extremity reconstruction.

Greater trochanter and olecranon

The greater trochanter and the olecranon are potential sites of cancellous bone harvest, specifically when small amounts are needed. The harvest technique is similar to a bone biopsy. A small incision is made overlying the area of interest, dissection is carried down to the bone, and the periosteum is removed from the desired area. An osteotome can be used to transect the cortex or a small drill bit can be used to create perforations in an elliptical pattern, which then can be connected with an osteotome. Through this opening, cancellous bone can then be harvested with a curette. After completion of the harvest, the cortical bone piece can be reinserted, or if need be, can be used as part of the graft. Hemostasis is achieved using gelfoam and

Fig. 18.11 Tibial bone grafts. (A) Incision for removal of the graft. (B) Removal of the graft with an osteotome.

thrombin. A layered closure is performed and a compression dressing applied.³⁷⁶

Rib

Rib can be used as graft or as a vascularized transfer. Rib grafts are flexible, which allows for easy bending and wire fixation. Also, rib integrates well to recipient bone. However, ribs are fragile and do not allow for stable screw fixation. Furthermore, the amount of cancellous bone is minimal and a second harvest is implausible due to poorly regenerated rib.

When harvesting rib, short skin incisions should be used and one rib should be skipped to preserve contour and stability of the thoracic wall (Figs. 18.12, 18.13). If possible, the surgeon should avoid subcutaneous dissection and transection of the rectus muscle. Also, one must be cognizant of bleeding from the intercostal vessels as well as air leaks. The harvest can be performed with the patient in the supine or lateral position. The skin incision should be located over the rib that is to be harvested or over the skipped rib if two ribs are required. Dissection is carried down to the rib, and the periosteum is incised longitudinally on the lateral aspect of the rib. Subperiosteal elevation should then be performed up to the costochondral junction. The length of the rib to be harvested is determined

based on the amount needed: a long segment from one rib is preferred over a short segment from two ribs. If cartilage is needed, it can be included in the harvest.

After harvest, the wound should be irrigated and examined for an air leak and then closed in a layered fashion. This takes place by suturing the edges of the periosteum and performing a layered closure of the muscles, subcutaneous tissue, and skin. A suction drain and local pain pump can be added if the surgeon desires.

The associated donor site morbidities and risks include pneumothorax, which can easily be prevented if careful and proper technique is used. In addition, the chest wall might become deformed if consecutive ribs are harvested. Postoperative breathing difficulties secondary to pain can affect postoperative recovery time. Overall the complication rate is low but varies within the literature. Complications may include pain, intraoperative bleeding and air leaks, secondary bleeding, and rarely, chest wall deformities or scoliosis.³⁸²

Calvarium

Calvarial grafts are ectomesenchymal, with a rich diploic vascular system that allows for rapid revascularization of the haversian systems. This facilitates osteocyte survival, leading to less resorption and increased structural maintenance.³⁸³ Calvarial grafts are ideal candidates for calvarial, midfacial, nasal, and orbital reconstruction.³⁸⁴ They are obtained as split- or full-thickness grafts. In young children, however, a split graft may not be feasible because of a thin calvarium. Harvest can occur via *in situ* splitting of the outer table or full-thickness harvest and on-the-table splitting to increase the surface area of graft available.³⁸⁵ It is important to use correct instruments

Fig. 18.12 Ribs 5–7 are the most commonly used donor ribs. (From Tessier P, Kawamoto H, Matthews D, et al. Taking long rib grafts for facial reconstruction – tools and techniques: III. A 2900-case experience in maxillofacial and craniofacial surgery. *Plast Reconstr Surg.* 2005;116:385.)

that are functional (Fig. 18.14). The surgeon must be aware of the location of the sagittal and coronal sutures, as the corticotomy should not occur less than 1 cm from the coronal suture or less than 1.5 cm from the sagittal suture. It is additionally important to locate the perforating vessel posteriorly near the sagittal suture.

The technique of calvarial bone graft harvest includes a coronal incision that is made through scalp and galea. The pericranium is then incised and elevated. Bone wax and/or gelfoam can be used to halt bone bleeding. The landmarks include the coronal suture, the sagittal suture (with its posterior perforating vessels), the anterior temporal crest, and the

intraosseous lateral vein. When taking a split *in situ* outer-table graft, the design can be outlined and traced with an oscillating saw followed by burring until diploe is seen. The alternating straight and curved osteotomes are used to split the calvarium. After the splitting of the outer table, further strips of diploe can be harvested until the inner table is encountered specifically at the thicker, posterior border near the lambdoid suture. If during this process the dura becomes exposed, it can be covered with bone chips. The pericranium can be closed over Surgicel® and the scalp should be closed in layers over suction drains.

There are several factors that make an intracranial approach for calvarial bone graft harvest a better option. Specifically, an intracranial approach should be undertaken in children with a thin calvarium, when a large graft is needed, in a patient with an irregular skull shape, or if, for graft design purposes, the inner table is more feasible. Availability of a neurosurgeon is recommended for this approach. Once the full-thickness piece is obtained, it can be split on the back table. One should not use a saw but rather an osteotome to reduce the waste of bony substance and to reduce heat damage to the graft. It is important to make sure that no cerebrospinal fluid leak is present and that hemostasis is achieved. One split segment is returned to the donor site; the other is used for reconstruction.

Overall, complications are rare (0.25%). Intraoperative incidents such as bone bleeding, dural bleeding, and dural laceration are usually controlled during surgery. Postoperative complications include minimal pain and occasional paresthesia, subscalp hematoma and calvarial irregularities, infection, and rare brain injury with transient neurological sequelae.³⁸⁶

Vascularized bone flaps

Vascularized bone flaps avert the reparative phase of nonvascularized grafts and do not depend on recipient bed vascularity. Specifically in circumstances of prior radiation, extensive trauma, or chronic scarring, vascularized bone flaps are superior to nonvascularized bone grafts.^{387–390} The survival of osteocytes in vascularized bone flaps leads to a decrease in the remodeling process during revascularization as well as the maintenance of bone mass and strength.^{391–394} Other advantages include increased blood flow to compromised recipient sites; utilization of composite tissue flaps, including skin, muscle, and nerves; and the growth potential when including a growth plate in the flap.^{395–400} An important indication for the use of vascularized bone flaps is segmental defects of greater than 6–8 cm after traumatic or oncologic bone loss; composite tissue loss; bony nonunion; avascular necrosis; osteomyelitis; or biologic failure.^{401–404}

Vascularized iliac transfer

The ilium, also a great source of graft material, has a robust periosteal blood supply in addition to the nutrient artery. Many studies have evaluated the best blood supply to the ilium.^{405,406} The superficial circumflex iliac vessels are often utilized in conjunction with a groin fasciocutaneous flap, but the deep circumflex iliac vessels offer a better blood supply to the bone (Fig. 18.15). Furthermore, a piece of vascularized iliac crest can be harvested in conjunction with the anterolateral thigh flap based off the lateral femoral circumflex system, with the ascending branch giving a small vascular pedicle to

Fig. 18.15 The deep circumflex artery vascularized bone flap. Vascularized bone based on the deep circumflex iliac artery and vein (DCIA/DCIV) is harvested and can be taken with an overlying skin paddle.

Fig. 18.16 The fibula free flap. Vascularized fibula is based on the peroneal artery and vein pedicle and can be raised with or without an overlying skin paddle.

the anterior superior iliac crest.^{407,408} Details of vascularized bone transfers can be found elsewhere in this series.

Vascularized fibula

The free fibula transfer is utilized mainly in mandibular and occasionally in midface reconstruction as well as for long-bone defects or nonunions. The fibula provides a straight piece of cortical bone up to 30 cm. The principal blood supply is via the nutrient artery, a branch of the peroneal artery with a diameter of 1.5–3 mm (Fig. 18.16). The fibula is also supplied by periosteal branches from the peroneal artery proximal to the nutrient vessel and musculoperiosteal branches distally. Dissection is performed through an anterior or posterior approach and bone can be transferred with adjacent muscles (e.g., soleus, peroneal, flexor hallucis longus). Fasciocutaneous perforators supply a skin paddle up to 10×20 cm.⁴⁰⁹ Though the surgical steps are described elsewhere, it is important to leave 6 cm of fibula distally to maintain a stable ankle joint. Also, rigid fixation of the transferred bone at the recipient site will improve healing. Complications include instability of the ankle joint, persistent pain, neurological compromise, and wound breakdown. A skin graft may be required if a skin paddle was included. Various series have shown significant complication rates, approaching 20% to 50%.^{410,411}

A unique advantage of free vascularized fibula transfer is the ability to include the physis within the flap based on the anterior tibial artery and vein.⁴¹² This is particularly useful in children with a malignant bone tumor located in an area that requires extirpation of all or part of a long bone including the native growth plate.

Vascularized scapula

The vascularized scapular bone flap can be combined with a variety of possible composite flaps that include varying amounts of muscle and skin. The scapula can be transferred as vascularized bone based on the nutrient artery, which enters inferior to the lateral attachments of the acromion to the scapula plate. Chimeric free flaps containing vascularized scapula, as well as rib and/or iliac crest, are particularly useful for “hostile” defects, composite defects in the setting of cigarette smoking, radiation, or scarring.^{413,414}

The scapula bone flap can be harvested off the lateral scapular border based on the circumflex scapular circulation or off the medial scapular ridge also based on the circumflex scapular circulation as well as on periosteal blood supply.^{415–417} The scapular bone can also be based on the angular branch of the thoracodorsal system, which supplies the scapular wing.⁴¹⁸ The mean pedicle length of the circumflex scapular system is

Fig. 18.17 (A) The outer table of the parietal bone is harvested with a curved osteotome after a trough is created around the periphery of the bone flap. The blood supply of the bone flap is maintained by preserving the periosteal blood vessels in continuity with the superficial temporal artery system within the galea superficial musculoaponeurotic system and the deep temporal fascia. (B) Sutures passed between the overlying galea, periosteum, and calvaria are helpful in keeping the periosteum attached to the bone and preserving the blood supply.

7.5 cm. It can, however, be increased up to 13–15 cm by clipping the circumflex scapula perforators, which allows the bone to be supplied by the angular vessels, thus avoiding the need for vein grafts.⁴¹⁹

During flap dissection the teres major and minor muscles need to be divided, which can cause shoulder dysfunction. Another potential complication is scapular winging from division of serratus anterior. Vascularized scapular bone might offer an advantage over fibula or iliac crest in older patients in whom ambulation is essential for postoperative recovery.⁴²⁰

Vascularized rib

The rib provides a curved, malleable piece of bone up to 30 cm long that receives its vascular supply through nutrient and periosteal vessels. The nutrient vessel arises from the posterior intercostal vessels and the periosteal blood supply from various nearby sources (intercostal, internal mammary, lateral thoracic, and thoracoacromial). The overlying muscle, skin, and fat of each region can be transferred with the flap.⁴²¹ A composite flap can be particularly helpful for reconstruction of complex three-dimensional (3D) cranial defects.^{422,423} A dissection that includes the nutrient vessel within the flap requires thoracotomy, adding difficulty and associated risks. Therefore, most vascularized rib transfers are based only on the periosteal blood supply.

Vascularized calvarium

The vascularized calvarial flap is useful for unfavorable recipient sites (irradiated or scarred) as well as in midface reconstruction.⁴²⁴ An understanding of the anatomy of the temporoparietal region is important to utilize this area for reconstructions with vascularized bone. Calvarial bone is covered with pericranium, overlying temporal muscle,

temporal fascia (deep and superficial layers), subgaleal fascia, superficial temporal (temporoparietal) fascia, subcutaneous tissue, and skin. Different flap types based off the superficial and deep temporal system can be useful to reconstruct midface and other facial defects.⁴²⁴

A temporoparietal fascial flap can be harvested with parietal bone vascularized by periosteal vessels from perforators of the superficial temporal system (Fig. 18.17). A vascularized calvarial flap can also be harvested with a fused segment of the deep and superficial temporal fascial flap 2 cm above the orbital rim.³⁸⁵ This flap is based on the middle temporal artery. A third option is a temporalis myo-osseous flap, which transfers the temporalis muscle and distal periosteum with the underlying bone as one unit. This is based off the deep temporal vessels.⁴²⁵ The parietal bone can be harvested as a partial (outer table) or full-thickness flap while avoiding the sagittal sinus (Fig. 18.18).

The surgical steps include a preauricular incision extending into the hairline, the elevation of flaps and dissection down to temporoparietal fascia, and a decision of flap level elevation and flap harvest with the appropriate pedicle, as described above. The pedicle is dissected into the pericranium of the desired calvarial bone. The bone flap design is based on the defect and reconstructive needs of the patient. Multiple strips can be harvested for complex three-dimensional defects. Stable fixation of the cranial bone flap at the recipient site is essential for reliable early bone integration.

Principles of bone transfer

Principles of bone grafting must be understood to optimize outcomes. Knowledge of these principles arises from three components: individual experience, experience of others (literature review), and knowledge acquired from basic science research.⁴²⁶ There are general principles and specific

Fig. 18.18 The parietal bone donor site. (From Tessier P, Kawamoto H, Posnick J, et al. Taking calvarial grafts, either split in situ or splitting of the parietal bone flap ex vivo – tools and techniques: V. A 9650-case experience in craniofacial and maxillofacial surgery. *Plast Reconstr Surg*. 2005;116:55S.)

doctrines. The general principles include defining goals and priorities; taking into consideration the location, size, depth, and etiology of the defect; the quality of the surrounding tissue; presence or history of infection; pre- or postoperative irradiation; age and health of the patient; status of disease (control or palliation); and functional and appearance-related considerations.⁴²⁷ The specific doctrines include the harvesting of bone from areas with which one is familiar, contouring of the bone graft to fit the defect, fixing the bone graft in a tension-free manner, ensuring absolute graft immobilization, differentiating between child and adult grafts, avoiding contaminated sites, proper handling of the graft, ensuring adequate blood supply over the graft, and assessing graft take periodically.⁴²⁶

If the recipient site is compromised due to scarring, infection, or irradiation, or if greater biomechanical strength is required for segmental defects greater than 6 cm in a load-bearing area, a vascularized bone transfer should be considered. The maintained/re-established vascular supply to the transferred bone leads to rapid healing with less resorption and greater biomechanical strength.^{392,393}

Allogeneic bone grafts

A bone allograft is harvested from a genetically dissimilar individual of the same species. The use of allogeneic bone for reconstruction of large bony defects in the axial and peripheral skeleton has grown in the last decade due to improved methods for bone preservation and sterilization. Nonvascularized bone allografts are free of any viable donor cells after antigen extraction and autolysis. These acellular constructs therefore mainly act as a scaffold for ingrowth of recipient mesenchymal cells, which repopulate the donor

by creeping substitution. Advantages over autogenous bone grafts include an unlimited supply, a lack of donor site morbidity, and decreased operative time. Disadvantages include the lack of osteogenic properties in prepared allografts as well as the immunologic response of fresh bone allografts. Due to slow union, long-term fixation is required.

Although allogeneic bone is a reasonable option in cases of insufficient autogenous bone or when only very limited allogeneic bone is needed for reconstruction, autogenous reconstruction leads to better graft incorporation and outcomes.⁴²⁸ Allogeneic bone grafts can also be combined with autogenous grafts for defect repair.⁴²⁹ These hybrid grafts offer the pro-osteogenic properties of autogenous bone while minimizing the main drawbacks.

Processing and preservation

Allografts can stimulate the host immune system and therefore are prepared by removing all viable cellular components in order to minimize this immune response. The goal is to create a sterile, acellular, biocompatible, and osteoconductive product. During preparation and preservation within tissue banks, the allograft loses its osteogenic and osteoinductive properties.

Processing techniques include mechanical debridement, ultrasonic or pulsatile water washes, ethanol washes, antibiotic soaks, and terminal sterilization with moderate-dose (<20 kGy) irradiation. Larger doses (>30 kGy) are needed to neutralize significant viral loads, but will weaken the bone significantly.⁴³⁰ The preservation of allografts can be achieved with deep-freezing (−70°C) or freeze-drying. Freeze-drying may cause a larger decrease in bone strength compared to deep-freezing.⁴³¹

Risk of disease transmission

The risk of disease transmission from processed allografts is minimal due to extensive donor screening and testing as well as the acellular nature of the graft.^{432,433} The pathogens of main concern are human immunodeficiency virus (HIV), hepatitis B virus (HBV), and HCV. Using donor screening recommendations, the transmission risk for HIV is estimated to be one in 1.67 million.⁴³³ However, this risk is probably lower with current screening and processing techniques.

Immunogenicity

Host immune reactions caused by allografts depend upon the degree of antigen mismatch between donor and host and the process of graft preparation. The immune system responds to fresh allografts via humoral and cell-mediated mechanisms; fresh frozen allografts, however, predominantly activate the cell-mediated immune system. The cell-mediated response is due to mismatch among cell surface major histocompatibility class (MHC) I and II antigens. Interestingly, freeze-dried allografts elicit only a minimal immune response.⁴³⁴ Signs of graft rejection, which are not as apparent as in solid organ rejection, include resorption and mechanical dysfunction. Chronic rejection may cause impaired allograft remodeling due to the sequestration of the implant in a fibrous capsule. The rejection process can be diminished by cyclosporine administration.⁴³⁵

Incorporation of allograft bone

The phases of allograft incorporation are similar to fracture repair. They include an initial limited inflammatory response with increased vascularity, followed by resorption, bone formation and remodeling. Cancellous bone is incorporated quicker than cortical grafts. The biomechanical strength of allografts after incorporation is lower than that of autografts, and this needs to be taken into consideration when reconstructing weight-bearing bones.

Formulations of allogeneic bone grafts

There are several formulations of allograft bone available including DBM, morselized cancellous chips, cortical and corticocancellous grafts, and whole bone segments. Demineralized bone preparations are not osteogenic, but they are osteoinductive and provide scaffolding upon which new bone can be formed.^{436–438}

Xenogeneic bone grafts

Xenografts are taken from a genetically different species. They undergo a high rate of resorption, and their immunogenicity, specifically due to matrix and serum proteins, limits their clinical utility. Deproteinized and defatted xenograft preparations demonstrate decreased immune stimulation but also demonstrate destruction of BMPs and other growth factors. Xenogeneic grafts are clearly inferior to autografts and allografts.⁴³⁹

Bone substitutes

Alloplastic cranioplasty is a concept as old as trephination. From the Incan use of precious metals, to the first documented use of a synthetic material to repair a cranial defect (Fallopian,

16th century), to Meekeren's use of canine bone in a human subject, the quest for a suitable nonautologous material has been ever present.⁴⁴⁰ The ideal bone substitute has the following characteristics: (1) chemically inert; (2) hypoallergenic or incapable of inducing a foreign-body reaction; (3) easily contoured; (4) stable and durable shape retention; (5) noncarcinogenic; and (6) capable of incorporation into or replacement with living tissue from the recipient. Although this ideal has not been achieved, several products are available and are discussed below. The following discussion is based upon the three broad categories of substitutes used in clinical practice: (1) cement pastes; (2) biomaterials replaced by bone; and (3) prefabricated polymers. Finally, we discuss scaffold biomimicry used for the engineering of osseous tissue.

Cement pastes

Calcium phosphates

Resembling the inorganic form of bone, hydroxyapatite and related composites have been available for FDA-approved clinical use since 1994. Calcium phosphate substitutes have supplanted calcium sulfate variants due to their closer resemblance to bone, higher biocompatibility, and tendency to undergo less resorption. Two main forms are available for use: ceramic pastes and cement pastes. Ceramic hydroxyapatite constructs (e.g., Interpore, Interpore International, Irvine, CA), although difficult to mold, demonstrate less resorption and better osteoconduction than their cement counterparts, as demonstrated in a series of animal experimentation.³⁰⁰ These authors were able to demonstrate that the higher the pore size, the greater degree of osteoconduction and osteoinduction, as substitutes composed of pure ceramic hydroxyapatite, or cement forms of higher TCP (80% TCP/20% hydroxyapatite) exhibited greater replacement by lamellar bone histologically.³⁰⁰ The latter formulation was osteoinductive by virtue of the relatively high TCP content that yields to resorption and replacement by macropores. The cement form of this material has been quite popular, due to its biocompatibility, malleability, and relative ease of handling. Due to the limited scope of this chapter in this regard, only two major commercially available forms of bone cement will be discussed: BoneSource and Norian. The reader interested in further review is directed elsewhere.^{441,442}

BoneSource

The first commercially available calcium phosphate cement,⁴⁴³ BoneSource (Stryker Leibinger, Inc.) is based on a mixture of tetracalcium phosphate and dicalcium phosphate dehydrate and activated with water at a 4:1 ratio prior to use. After an isothermic reaction, the resulting paste can be contoured on the field, setting into pure hydroxyapatite within 20–25 minutes. Final set time is 4–6 hours.⁴⁴⁴ A dry operative field is mandatory for this biomaterial to reach its final cured state. In this state, BoneSource achieves a compressive strength of 50 MPa and a diametral strength of 8 MPa.

BoneSource has been used over the years in numerous applications on the craniofacial skeleton. Providing one of the largest series to date, Burstein and colleagues⁴⁴⁵ reviewed their experience with this product in 61 patients

retrospectively (20-month mean follow-up). Inlay and onlay grafting were performed over a 3-year period. Postoperative complications were present in 11% of patients, mainly seromas. Interestingly, the authors used slow-release antibiotic therapy (1 g cephalosporin mixed with 10 g of cement prior to use). In another large trial in cranioplasty patients ($n = 103$), an overall infection rate of 5.8% was achieved.⁴⁴⁶

Norian SRS/CRS

Norian (Synthes, Inc.) is a unique carbonated calcium phosphate that mimics the inorganic phase of bone. Conferring solubility at a low pH, Norian has the theoretical advantage of resorption and replacement by true bone.⁴⁴⁷ This calcium phosphate cement is produced intraoperatively by mixing a base powder (monocalcium sulfate, monohydrate, α -TCP, calcium carbonate) and a solvent containing sodium phosphate at room temperature.⁴⁴⁸ After a 5-minute interval, the material becomes implantable, and continues to cure for approximately 24 hours to become a microporous polycrystalline apatite with a maximum compressive strength of 50 MPa and tensile strength of 2.1 MPa. For comparison, the compressive and tensile properties of cancellous bone are 1.9 and 2.42 MPa, respectively.⁴⁴⁸ The commercial product is available in regular and fast-setting formulations.

FDA-approved since 1998, Norian CRS has now been subject to long-term clinical outcome analysis. Providing the largest series specific to this bone cement in the context of craniofacial surgery, Gilardino and colleagues⁴⁴⁹ report a rather substantial complication rate (26% overall) when using this product, regardless of the type of cranioplasty (onlay, full-thickness inlay). The majority of complications were infectious, attributable to the sheer amount of material used, or its use in a contaminated field. Stratifying according to type of cranioplasty (inlay versus onlay), the authors report the following limitations with Norian: (1) increased trending complication rate when >25 cm² inlay defects are reconstructed with this bone cement; (2) statistically significant increased complication rate when onlay constructs were placed in areas of high bacterial contamination (paranasal sinuses). Such results indicate that this bone cement, not dissimilar to others, is likely not osteoconductive, as supported by several experimental studies.⁴⁵⁰

Osteoactive materials

Osteoactive materials include bioactive glass (NovaBone®, Porex Surgical Inc.) and DBM. Composed of silica dioxide, sodium dioxide, calcium dioxide and phosphate, bioactive glass confers its osteogenic properties when these components are mixed together to form an apatite surface layer. This layer recruits and stimulates osteoprogenitor cells to produce cytokines that have an autocrine and paracrine effect. Osteoblasts proliferate and differentiate on this surface, leading to new bone formation. In turn, the particulate glass is resorbed via osteoclastic activity.

The formulation that comprises DBM is based upon the landmark work of Urist and Strates⁴⁵¹ and Reddi and Huggins.⁴⁵² To date, manufacturers produce this bone substitute with the standard methodology: human cadaver long diaphyses are morselized to 250–600- μ m particle sizes, demineralized in 0.6 N hydrochloric acid, and washed with

deionized water, ethanol, and ethyl ether. In contrast to bioactive glass, DBM contains trace amounts of BMP, which makes this biomaterial both osteoconductive and osteoinductive. At baseline, however, DBM alone is hard to handle, making it difficult to apply clinically. In order to improve handling characteristics, manufacturers have added various types of carriers to the formulation (e.g., glycerol, gelatin, calcium sulfate). Therefore, not all preparations of DBM are the same. To this end, Acarturk and Hollinger⁴⁵³ have performed comparative analysis of all the different DBM products. In an athymic rat critical-sized calvarial defect model, they found that there was indeed a differential bone-regenerative effect among the different formulations. One unifying principle was that those formulations that handled better (DBM + glycerol (Grafton, Osteotech, Inc.), DBM + hyaluronan (DBX, Synthes US)) demonstrated statistically significant higher bone formation than other groups, as assessed by histomorphometry. Overall, however, the bone-regenerative capacity was not as robust as the authors predicted, which could be related to not achieving the threshold quantity of particulate DBM required for complete ossification of the defect. There are numerous formulations of DBM that have been utilized for a variety of applications as reviewed by Gruskin and colleagues.⁴⁵⁴

Prefabricated polymers

Methylmethacrylate

An acrylic-based construct, methylmethacrylate^{455–457} forms when a powdered mixture of methyl methacrylate polymer, methyl methacrylate-styrene copolymer, and benzoyl peroxide monomer is combined. The reaction is caustic, leading to an exothermia that approaches 85°C and pungent fumes that are carcinogenic. In fact, the premixing recommendations of this construct recommend use in an approved fume hood. After mixing for 8–10 minutes, the polymerization process yields a rigid, durable material that can be contoured, is radiolucent, and can be fixed rigidly to the cranioplasty site. Advantages of this material include a relatively low cost, possibility of *in situ* contouring, and lack of biodegradation. A prefabricated, customized, modified version of this material (Hard Tissue Replacement, Biomet Corporation, Jacksonville, FL) is composed of polymethylmethacrylate-polyhydroxyethyl methacrylate and available based on preoperative computed tomography data.⁴⁵⁸ This hard tissue replacement polymer has been utilized in cranial defect reconstruction, chin and malar augmentation, and correction of the temporal “hourglass” deformity.⁴⁵⁹ The major drawback to acrylic-based resins, and in particular methylmethacrylate, is the substantial exothermic reaction involved in curing, which *in situ* can lead to severe thermal tissue injury. The cured, rigid substance has a high bacterial adhesion profile, and thus the high incidence of infected cranioplasties when using this substance.

Medpor

A high-density, porous polyethylene construct (pore size 100–250 μ m), Medpor has gained some popularity in the reconstruction of select sites of the craniofacial skeleton. Current applications include nasal/malar augmentation, orbital floor reconstruction, genioplasty, and cranial augmentation. In this last application, Medpor has been found to augment

successfully resorptive areas of the craniofacial skeleton (e.g., temporal fossa). Due to its porous nature, this implant permits native tissue ingrowth and therefore may provide some resistance to infection. Other advantages include the ability for intraoperative contouring, and customized prefabrication based on three-dimensional volumetric data (DICOM) from computed tomography. Despite these benefits, there are clear disadvantages to this material (risk of infection, exposure, extrusion) that limit its use to well-vascularized recipient sites. As with all alloplastic cranioplasties, an irradiated field bears a relative contraindication from the use of this implant. Recently, Medpor has been successfully used in conjunction with 3D modeling for reconstruction of a suprastructure maxillectomy defect.⁴⁶⁰ Indeed, the use of 3D modeling and virtual surgical planning may improve surgical outcomes and aesthetics when using alloplastic implants for complex craniomaxillofacial defects.

Experimental scaffolds

Appreciation for the role and structure of native ECM as well as pitfalls associated with current techniques for bone regeneration have prompted investigation of experimental scaffolds to augment osseous engineering strategies. Biomimetic scaffolds can be used to improve delivery and containment of progenitor cells and growth factors to the defect. These complex 3D structures serve a role analogous to native ECM.⁴⁶¹ Effective scaffolds are biocompatible, exhibit mechanical properties similar to the surrounding tissue into which they are implanted, and support cellular adhesion and proliferation. Additionally, scaffolds must allow for ingrowth of autologous tissue (i.e., be biodegradable). Many experimental scaffolds have been studied, including polymer-based, CaP-based, and composite-based scaffolds. An in-depth review of significant recent research can be found elsewhere.⁴⁴²
